SECTION 1

CPU BOARD

INTRODUCTION

This section describes the circuitry of the CPU board supporting COS versions 3.0, 3.4 and 4.0. There is no hardware alteration between the three COS version CPU boards, although differences do exist on boards supporting COS 2.3 or earlier. No attempt is made to document these early boards as so few are now in use.

CIRCUIT DESCRIPTION

(Circuit: 380Z : CPU/RAM

380Z : CPU-2)

The CPU board incorporates:

- a Z80-A processor
- processor support
- bus control/buffering
- two fully supported 16K banks of dynamic RAM
- space for three 2716/2708 monitor EPROMS (fully supported)
- system clock
- an 8-bit parallel bi-directional port (user port).

Processor and Processor Support

(Circuit 380Z : CPU-2)

The Z80A processor is clocked at 4MHz from the system clock. Interrupt request sequences are not used by the operating system, but the 50-way bus allows for external interrupts to be serviced (J3-30). Bus Request/Acknowledge (Req/Ack) sequences are not used by the operating system, but, again, the 50-way bus allows for future expansion (DMA etc.).

Non-maskable interrupt (NMI) routines are used by the operating system to service the "single-step" Front Panel command. NMIEN- is derived from a bit in system port 0 on the VDU board, which then enables counter IC 1 (LS90). On the eighth M1 cycle after NMIEN- becomes active 'low', an active 'high' output from the counter is inverted to produce active 'low' NMI-. During this period, NMIEN- must be disabled within eight M1 cycles or else NMI is activated again and a loop is established. The repetition of NMI requests is a very common fault condition associated with "garbage" on the screen.

After a processor reset, system port 0 is cleared and NMIEN- is active. EPROM 0 is mapped to address 0000H-0800H on page 0 where instructions are located within the first two M1 cycles to initialize system port 0 and prevent NMI. If these instructions are not executed, due to a fault condition, the repeated NMI results in a loop in which the screen is not cleared and "garbage" is displayed.

The reset circuitry lies mainly on the VDU board where a 2400Hz signal is synchronized with the M1 cycle so that the processor only receives active 'low' reset during M1 cycles. This ensures that RAM contents are not corrupted during reset. In the absence of reset, due to a CPU board fault (which usually results in "garbage"), M1 should toggle to enable reset pulses on the VDU board (power-on reset excluded).

When power is applied to the Z80, M1 is inactive until the processor is reset. Absence of power on 'reset' reaching the processor will normally result in inactive M1 and no response to the RESET button. The situation can be very "Catch 22" if this is not borne in mind when tackling faults around this circuitry. Bus reset is buffered by a transistor to drive the bus; processor reset is inverted by a segment of IC 20 to drive pin 26 of the Z80A CPU.

One wait cycle is inserted every memory cycle in the following way: on the first rising edge of the system clock, after MRQ- becomes active 'low' (start of memory cycle), MRQ- is clocked through D-type flip-flop IC 22 and appears as a 'high' on the Q-output (pin 8). One system clock cycle later it appears, as a 'low' on the Q-output pin 5. Both outputs are then NANDed by IC 20. The output of IC 20 is WAIT- and is exactly one system clock cycle in duration with a delayed (one clock cycle) inverted version of itself produced in the other half of IC 22. The output of IC 20 pin 13 is WAIT- and is exactly one clock cycle in duration.

In the absence of interrupt requests, and if the HALT- output of the processor is active 'low', the processor has executed a halt command: the system will be irretrievably locked, and can only be restarted by an external interrupt or system reset. HALT- is available on the 50-way bus for future expansion.

To produce the signal NOT(M1+RD), two high-speed diodes are used in a diode resistor AND gate to minimize propagation delay. The signal is used to select the direction of transfer of data through bi-directional tristate buffers, ICs 14 and 15 (74LS241).

Bus Control and Buffering

(Circuit 380Z : CPU-2)

Apart from processor control signals, the main bus can be divided into two sections:

- An 8-bit bi-directional data bus (BD0-BD7)
- A 16-bit uni-directional address bus (BA0-BA15).

The data bus is buffered from the processor by ICs 14 and 15. All 8 bits

are transferred directly to the 50-way bus (J3 3-10) and the 37-way bus to the VDU board (J2 16-23). With the exception of external bus Request/Acknowledge cycles, the processor controls the direction of transfer of data in the bus, as described under 'Processor Support', above. In response to an interrupt request M1- can occur without RD- during data transfer to the Z80, so it is necessary to control the bus direction by using the ORed function of M1- and RD-. All devices which drive the data bus have tristate output stages.

The address bus is buffered from the processor by ICs 8, 9, and 10. All 16 bits are transferred directly to the 50-way bus (J3 11-26) and the least significant 11 bits (BA0-BA10) are transferred to the VDU board via the 34-way bus (J2 24-34). With the exception of external bus Request/Acknowledge cycles, the processor drives the bus exclusively, and the address buffers are constantly enabled.

EPROM and EPROM Support

(Circuit 380Z : CPU-2)

There are three 24-pin sockets on the CPU board so that either 2716 or 2708 EPROMS (by link connections) can function in any socket. The sockets are generally known as 0, 1, and 2. COS (monitor program) occupies at least 4K of addressable ROM space and always occupies ROM in sockets 0 and 1 (COS 3.0, 3.4) or all three sockets (COS 3.0 [2708's in 1 and 2], COS 4.0 and COS 4.2 [2716's in 0, 1, and 2]).

Eleven address lines are required to uniquely address 2K of ROM. The least significant addresses BA0-BA10 are used to select the address within ROM to be read. Coarse address decoding is performed by PROMs M and P (ICs 13 and 19) using the most significant six bus address lines and one page bit. In this way, ROMn ENAB- is generated and each ROM is mapped into address space within a 64K page. Two pages are currently available: ROM 0 is mapped at 0000H on page 0 to execute code on power-up, and normal 380Z page 1 mapping is selected on setting the Page Sel bit in system port 0.

Once ROMn ENAB- is active (follows MRQ- timing) the 8-bit word stored at the specified address within the EPROM is transferred to the data output lines DO -D7, and buffered onto the data bus by IC 11 (tristate unidirectional). IC 11 is enabled by the ANDed function of MEMRD- and ROMRD- (derived form ICs 17 and 19), which ensures that write operations to address space occupied by ROM does not cause a data bus crash. Space occupied by ROM is transparent to write operations.

Dynamic RAM and RAM Support

(Circuit 380Z : CPU/RAM)

There is space on the CPU board for up to 32K of dynamic RAM (4116 or similar) organised as two banks of $16K \times 1 \times 8$ bits. Bank 0 must contain $16K \times 1$ -bit RAM but provision is made both by hardware and software for bank 1 to be empty, or to accept $4K \times 1$ RAM, or to accept $16K \times 1$ RAM.

A complete diagram showing RAS and CAS timing within all memory cycles is

shown in figure 1.1. Measurements are taken when executing the following code:

0100		LD	HL,1000H
0103	LOOP:	LD	(HL),A
0104		JR	LOOP

Fourteen address lines are required to uniquely address each location within a 16K bank of RAM. Bus addresses BAO to BA13 are applied to the inputs of two 2-1 multiplexers (ICs 5 and 6.) With the exception of a refresh cycle, BMRQ- is clocked on the first rising edge of the system clock, after MRQ- becomes active through D-type flip-flop IC 24, to a 'low' on output Q (pin 5). This output is used to switch the multiplexers between row and column addresses at outputs MAO to MA7. CAS becomes active after a delay (IC 16 plus a 1000pF capacitor) allowing time for addresses to settle and for RAM to process the row address. RAS is generated by producing a coarse address decoded output of PROM M (IC 13) using BA14 to 16 and one page bit to map one bank of RAM to address space within a 64K page. This output selects the bank of RAM for a given 16-bit address and is NANDed with BMRQ- to produce RAS active from the falling edge of MRQ-. CAS is applied common to both banks of RAM. RAS is active during read/write cycles only to the bank being accessed. The precise address within a bank of RAM is selected by the multiplexed addresses MAO to MA7.

LINKS L10-L12 adjust address multiplexing to provide outputs suitable for driving $4K \times 1$ RAM (4027, etc.)

Data input to the RAM is taken directly from the data bus. MEMWR- is active to instruct RAM to accept data during the memory cycle only during a RAM-write operation (IC 17).

Data output from the RAM is buffered by IC 2 and passed onto the data bus only when RAMRD- is active. RAMRD- is generated by producing a coarse address mapped output from PROM M (IC 13) which is ANDed with MREQ- and BRD-, to produce RAMRD-, only during read operations from RAM. RAMRD-timing should follow BMRQ- timing exactly during RAM read operations.

RAS-only refresh is maintained on all banks of RAM in the following way:

- CAS is inhibited by applying a 'high' on pin 2 of IC 17, thus ensuring that corruption of data does not occur during refresh.
- PROM M (IC 13) produces an output enabling RAS of both banks during the MRQ- signal active period (see figure 1.1).

System Clock

(Circuit 380Z : CPU-2)

IC 23 (4069) is used in a crystal-controlled 8MHz feedback-oscillator which produces a near-sinusoidal waveform on pin 10. Other segments of IC 23 are used to square the 8MHz clock; this is then taken to the VDU board (J2-9) and to IC 24 which is wired as a divide-by-two counter with output on pin 9

at 4MHz. This output is buffered onto the 50-way bus (J3-40) by IC 21, and also buffered by a different segment of IC 21 onto the processor. BCLK is the 4MHz system clock and is in phase with the 4MHz clock to the processor.

Memory-Mapped Port Decoding

(Circuit 380Z : CPU/RAM)

Coarse decoding circuitry is used to support memory-mapped ports, such as system port 0. The screen mapping is also coarsely decoded in this way. Using the more significant address lines and one page bit, PROMS 13 and 19 produce an output when the address bus contents correspond to either screen address or memory-mapped port addresses. Finer decoding of port addresses is carried out by IC 7, which gives an output IOSEL- when the address bus content is within the block of 4 port addresses. Both VDU SEL- and I/O SEL- are taken to the VDU board on the 37-way bus.

User Port Latches

A buffer (IC 3) and a latch (IC 4) on the CPU board, together with a 20-way connector, form the user port interface. Input/output is taken directly from the data bus, and control circuitry is found on the VDU board.

SECTION 2

VDU-40 BOARD

INTRODUCTION

This section details the circuitry of the VDU board supporting CPU boards with COS versions 3.0 and 3.4. Early versions of the VDU board may have hardware modifications to the latest circuit specification. No attempt is made to document anything other than the current 40-character VDU board.

CIRCUIT DESCRIPTION

(Circuit Diagrams: 380Z : VDU-1, Keyboard and Cassette Interfaces,

Ports and Video Memory.

380Z : VDU-2, Video Generation.)

The VDU board comprises:

Screen generation hardware

- 1K of static screen memory
- Cassette-handling hardware
- CPU reset circuitry
- Keyboard port
- Three system ports
- User port control circuitry.

Screen Generation Hardware

(Circuit 380Z : VDU-2)

Both IC 30 (74LS393) and IC 33 (74LS73) comprise a 9-bit binary counter clocked at 8MHz from the CPU board. The 9-bit outputs are column counts CC0 to CC8. The column count is used to define a horizontal screen position. CC4-CC8 are used to count character positions along a screen line (row) and are fed into the line waveform generating PROM (IC 31, coloured green). The line PROM produces signals LINE ACCESS, LINE BLANKING, LINE SYNC., and a count output to clock the line counter. The signals are then latched by IC 34 on the rising edge of CC3. The LINE COUNT output clocks a 9-bit binary row counter (ICs 32 and 37) the outputs of which (RC0-RC8) define row positions within the screen. RC1 to RC8 are used by the FRAME PROM (coloured yellow) to produce signals FRAME RESET, FRAME BLANKING, FRAME SWITCH, and FRAME ACCESS.

The LINE and FRAME BLANKING signals are mixed by IC 25/1,2 to give a composite blanking signal on IC 25/3.

FRAME SWITCH is used by the line PROM to invert line sync pulses and double

their frequency during FRAME SYNC to maintain convention with television video sync signals.

LINE and FRAME ACCESS are available as bits in read port 1 and can be tested to open the Video RAM during line/frame blanking.

A 7-bit word read from the video RAM is decoded in the character generator IC 27 and identifies a unique character. The five outputs, Y1 to Y5, are the row dot pattern corresponding to the row within the character selected by inputs RCO to RC3. Y1 to Y5 are latched by IC 28 at the start of each new row within a character, then fed to IC 29 (8-to-1 binary select demultiplexer); CCO to CC2 select which of the five column bits to transfer to output pin 5 (IC 29). In this way, row data is shifted serially through IC 29 and becomes video information on pin 8 of IC 43 (if not inhibited by GRAPHICS- on pin 11, IC 43).

Video information is inhibited by composite blanking in IC 38, and VDU ON+ in IC 40. (VDU ON- is used to open the screen to write to the video RAM and is normally only active during screen blanking, to prevent flicker. VDU ON is under software control, and is a bit in system port 0). Video information, VIDG, is conditionally duplicated (condition = white graphics) to form VIDW. If VIDW is inhibited (grey-active) the video information formed by adding (analogue) VIDG & VIDW is half the amplitude that would be generated with VIDW active, and grey intensity results.

()

D1, D2, and R25 form the video/sync mixer. The video output stage is a common collector transistor impedance buffer. Output impedance is 75 Ohms and level 1V peak to peak composite video information, -ve sync. Power for the video output stage is derived from the 12V rail via R35 and D3. A simple UHF modulator accepts composite video input and produces a UHF modulated copy. Carrier channel is around channel 36.

The character generator (IC 27) is a TEXAS 74LS262 which has a teletext-compatible character set and is an industry standard. It accepts ASCII-coded input for codes in the range 0 to 128. Above these values, codes are interpreted by the VDU board as graphics characters. These are generated by the dual 4-to-1 binary select multiplexers, IC 35 and IC 42 (latch), from information encoded in the hardware of the logic array formed by ICs 38, 39, and 40. Graphics is selected from MD7 (ASCII codes greater than 128) and grey intensity is selected from MD6.

1K Static Screen Memory

(Circuit 380Z VDU-1)

One page of video information is stored in static RAM on the VDU board to enable screen displays of 40 x 24 characters. To uniquely address 40 characters in a line, six address lines are required, and, for 24 lines in a frame, 5 address lines are required. Thus, to specify each unique location on the screen as part of a rectangle would require 11 address lines. Using 1K static RAM, only 10 address lines are available, so it is necessary to address the screen as a 5x5 address square, and "move" part of the square to a screen position such that a 40x24 shape screen results.

The hardware of the VDU board automatically accommodates the transfer of screen address position by detecting when CC8 is valid and adjusting the output of multiplexer IC 14 accordingly. With the exception of this complication, multiplexers 11, 12, and 13 select between access to the screen for reading (row and column address specify character position) and access to the address bus for writing (a character written to a unique address corresponds to a character position when read back by the screen). Ten address lines, MAO-MA9, address the 1K of video RAM.

Data input is taken directly from the data bus, (BDO to BD7), and is written to the RAM when VDUWR- is decoded by IC 25.

Data output from the RAM forms the bus MD0 to MD7 which feeds the character generator and graphic generator circuitry. Provision is made to read the video memory to the data bus, BD0 to BD7, by opening the screen (VDU ON-inactive) and transferring the MD bus to the BD bus via tristate buffer IC 26.

Cassette-Handling Hardware

(Circuit 380Z : VDU-1)

Binary counter IC 9 is clocked by a 16 us clock, CC6. It is wired as a divide-by-14 counter and the output is further divided by 2 and 4, yielding 2400Hz and 1200Hz on IC 9/10,11. These two clock frequencies are passed through active 'low' pass filters (IC 8) and appear as sinusoidal waveforms at the fundamental frequencies on IC 8/7,8.

The cassette recording format consists of selecting between cycles of 2400Hz and 1200Hz to encode serial information. The serial information to be encoded is generated under software control and appears as a bit in system port 0, SWITCH. SWITCH is converted to CMOS-compatible level via Q1 and drives the select input of a 2 - 1 analogue multiplexer (CMOS) IC 7. According to the level of SWITCH, either 2400Hz or 1200Hz is transferred through IC 7 and appears on IC 7/14 at a much reduced amplitude (approximately 100mV pk to pk) and via C1/R1 to connector J1-25 as CASSETTE OUT.

The cassette input is A.C., coupled via a low pass filter R3/R4/C2/C3 to a segment of op-amp IC 8 operated in open loop mode. Transitions between supply rails occur at the output pin 1 on each zero-potential transition on input pin 2. R11 converts the output level to be TTL compatible, and the signal produced is CASSETTE SIGNAL, which can be read as a bit in system port 2. Simultaneously, a bit is available in system port 2, CASSETTE VOLUME, which indicates adequate/inadequate signal strength on the cassette input line. Signal strength is detected by another segment of IC 8 wired as a simple comparator with a DC potential formed by R8 and R9. This amplitude detector is sensitive to phase and so the output can be used with CASSETTE SIGNAL to deduce the phase of the cassette input signal. All decoding of cassette data is carried out under software control by support routines within COS.

CPU Board Reset Circuitry

(Circuit 380Z : VDU-1)

• Power-on Reset:

When power is first applied to the system, a small amount of dedicated circuitry ensures reliable system initialization and does not depend on CPU board signals being present (e.g. M1). A 4.7 uF capacitor is charged to +5V via a 33kohm resistor. Until the voltage upon the capacitor develops to a TTL logic 1, the SET and RESET inputs of the J-K flip-flop segments in IC 44 are held 'low', and 2400Hz pulses are transferred unconditionally to output pins 15 (Q- active high) and 14 (Q- active low). These outputs are SYSTEM RESET (transferred to CPU board) and Q- is used to reset system port 0.

Manual Reset:

Users can manually activate the system reset by means of the RESET button. When the RESET button is pressed, J-K flip-flop IC 44/12K input goes 'high'. With SET, RESET, J, and K inputs 'high', the outputs toggle with the 2400Hz clock input (generated in the cassette-handling hardware IC 9/11). The 2400Hz signal produced is clocked through the second segment of IC 44 on the falling edge of BM1-, ensuring that reset pulses only reach the Z80 during an opcode fetch and that the contents of RAM are not corrupted. There is sufficient time between reset pulses to maintain refresh to the dynamic RAM in the system. System port 0 latch IC 1 is reset simultaneously with system reset.

System Ports, Keyboard Port, and User Port Decoding

(Circuit 380Z : VDU-1)

Coarse port decoding is carried out on the CPU board and the 4 ports are mapped to occupy the following positions within the memory map:

	PORT 0	PORT 1	PORT 2	PORT 3
PAGE 0	1BFCH	1BFDH	1BFEH	1BFFH
PAGE 1	FBFCH	FBFDH	FBFEH	FBFFH

Port 0 Read:keyboard port Write:system port 0

PORT 0 BIT ALLOCATION:

READ	BIT	WRITE
KBD BIT 7	7	PAGE SELECT (0=PAGE 0)
KBD BIT 6	6	CLR COUNTER (1=CLEAR)
KBD BIT 5	5	CTRL 2 (Cass. motor)

(Cont'd)

KBD	BIT	3	3	CTRL 1 (Cass. motor)
K BD	BIT	2	2	VDU ON- (1=Screen Open)
KBD	BIT	1	1	NMIEN- (0=NIM enabled)
KBD	BIT	0	0	KBD CLR+

Port 1 Read:counter Write:no port

PORT 1 BIT ALLOCATION:

READ		BIT	WRITE		
62.5	kHz	0	_		
31.25	kHz	1	-		
15.625	kHz	2	-		
7.81	kHz	3	_		
3.91	kHz	4	_		
1.95	kHz	5	-		
975	Hz	6	-		
487	Hz	7	-		

Port 2 Read:system port 2 Write:no port

PORT 2 BIT ALLOCATION

READ	BIT	WRITE
LINE ACCESS	7	-
FRAME ACCESS	6	_
CASSETTE SIGNAL	5	-
•	4	_
CASSETTE VOLUME	3	_
RESET BUTTON	2	_
1200Hz	1	-
KBD STROBE	0	-

Port 3 Read:user port Write:user port

IC 23 is used to uniquely decode each of the 4 ports using IOSEL- from the CPU board and BAO, BA1, MEMRD-, and MEMWR-.

The keyboard port functions as follows: A negative-going edge of a keyboard strobe clocks data into two 4-bit latches which form read port 0. KBD STROBE is also available as a bit in system port 2 (read port 2) and is tested to detect keyboard input. Keyboard data may then be read from port 0; the latches may be cleared by setting bit 0 in system port 0.

SECTION 3

VDU-80 BOARD

INTRODUCTION

This section details the circuitry of the 80-character VDU (VDU-80) board supported by COS 4.0. The board operates in two modes:

- 1. 24 lines by 80 characters
- 2. 24 lines by 40 characters

The circuit is complicated in mode 2 by the need to maintain hardware compatibility with the existing 40-character board.

CIRCUIT DESCRIPTION

(Circuits	:	VDU	80-1	80/40	VDU	TIMING/PORTS	
		V DU	80-2	80/40	VDU	MEMORY	
		VDU	80-3	80/40	VDU	BUS BUFFERS	
		V DU	80-4	80/40	VDU	OUTPUT)

Timing

(Circuits VDU 80-1, VDU 80-3)

The 80-character display requires a dot rate of 16MHz. However, to operate correctly in conjunction with the HRG board, the 16MHz must be synchronized with the system clock. It is derived from the 8MHz available at the 34-way connector. This signal is almost sinusoidal and is squared by IC CP (74L221). The two outputs of this monostable drive IC DP (74221) which produces pulses on both rising and falling edges. These are combined by EP (74LS02) to give the signal C16M. In 80-character mode, this signal should be at 16MHz with a 1:1 mark space ratio. In 40-character mode, alternate pulses should be missing.

The character rate, CRATE-, is generated by counter GP (74LS169A or 74LS168A or equivalent, but not 74LS668 or 74LS669), which counts down from 7 to 0 during each character. CRATE- indicates that the last dot of a character is being displayed and is used to enable the loading of various registers.

The main dividers GU (74LS393), FT (74LS390) and FV (74LS393) are similar to the standard 40-character VDU board. Their outputs drive PROMs FU, EU (74LS287 or equivalent) which generate blanking and synchronization signals. Separate vertical and horizontal syncs (VDRIVE and HDRIVE) are available for a "wire frame" type monitor. Note that all the PROMs have

4K7 SIP pull-ups on their outputs to allow use of open collector types without needing the "piggy-back" resistor network.

Hardware Scroll

(Circuit VDU 80-1)

Hardware scroll is performed by adding a number to the output of the row counter, modulo 24. This has the effect of scrolling the display by that number of lines. The number to be added is in the low 5 bits of CR (74LS377). This is memory mapped at FBFD. However, the port can only be written to when the screen is closed, so it cannot be done directly from the Front Panel. The addition is performed by ES (74LS283) and FR (74LS287).

Address Multiplexers

(Circuit VDU 80-1)

The VDU can be written to "transparently". That is, it is not necessary to wait until line or frame blanking takes place. This is achieved by cycling the memories twice per character, once to get the character and once for the CPU. The CPU and VDU addresses are multiplexed by AR (74LS157), CT (74LS257) and AT (74LS399). CS (74LS399) performs the translation from 32x32 to 24x40 as on the 40-character VDU board. The multiplexers CS and AT contain a latch on their outputs clocked twice per character. The remaining address lines are latched by DT (74LS175). When in 80-character mode, four address bits are latched in DU (74LS173).

Character and Attribute Memory

(Circuit VDU 80-2, VDU 80-3)

The characters are stored in CW (HM6116) while the attribute bits are held in BU and CU (2114). The characters are latched in DW (74LS273), and the attribute bits in part of AS (74LS374). The characters are read and written using DV (74LS245). When a character is written, the corresponding attributes are cleared. For this purpose, 1k2 pull-ups are provided on the data lines of EU and CU. When the attributes are themselves to be read or written, the data is passed through DR (74LS240).

The data bus buffers consist of BR (74LS373) and AQ (74LS244). BR is a latch to hold the data long enough for a write to take place when using the 'transparent' mode.

Character Generator

(Circuits VDU 80-1, VDU 80-2)

The character generator is the ROM EW (2516 or 2532) together with the RAM GW (HM6116P). The information from the character latch is applied as an address to these memories along with four bits from the row counters. The data is latched in the shift register GV (74LS166) from where it is shifted out as video information. The RAM portion of the character generator

allows for user-definable characters. To store these characters, both address (to select one row of the character) and data (the dot pattern for that row) must be supplied. The character generator can also be read back by the CPU.

Data is applied through EV (74LS245); the address is more tricky. The high eight bits must be latched in DW (74LS273) via DV (74LS245) by writing to a port at FBFE with bit 3 (CGSEL) of the control port at FBFC set. The remaining four bits are written to the latch DU (74LS173) which is also mapped at FBFE but which is only available when the screen is closed. (Note: The outputs of this latch are connected to the same lines as the outputs of the multiplexer CT (74LS257). This is because the same latch, DU, is used to supply some of the address bits to the character store when accessing the screen in 80-character mode.) The multiplexer ET (74LS399), which includes a latch, selects either the row counters (normal display) or DU (writing to character generator, or during a smooth scroll) as the source of the four low-character generator address lines.

Control

Control signals from the CPU are buffered by AP (74LS244). Whenever possible, signals are taken from the bus connector rather than from the 34-way connector. The bus buffer direction is controlled by logic contained in CQ (74LS27), DR (74LS02), and FP (74LS266).

BS (74LS155) is a decoder for the ports at FBFC to FBFF. The signals PORT3 WR- and PORT3 RD are sent back to the CPU to enable the user I/O port. The latches ER (74LS273) and CR (74LS377) supply miscellaneous control bits as shown on the diagrams. Half of AP (74LS244) is used to monitor KBDSTB, VBLANK and HCPUEN.

Keyboard

(Circuit VDU 80-1)

The keyboard port is CV (74LS374). As this cannot be cleared, a separate latch made from two gates in FQ (74LS132) is provided to catch the strobe. A filter (R11 and C5) is provided on the strobe line. One section of the Schmitt-trigger EQ (74LS240) is used to clean up the signal which is then differentiated by R9, R10 and C6 to provide a short pulse to set the latch. This allows the use of a keyboard which produces a level while a key is held, as opposed to a short strobe.

Reset

1

The reset circuit is similar to the current one (as VDU40)

Character Write Signal

The generation of the write strobe to the character store is complicated by the transparent access. When the CPU performs a write operation, it must be delayed until the memory has finished the current character access. One section of FT (74LS390) is used simply as a flip-flop to remember that a "write request" has occurred. This is synchronized to the VDU timing by

the latch DY (74LS374) and from the latched signal a write strobe is generated by the monostable BP (74221). This strobe also clears the latch FT.

CTC

The CTC allows interrupts to be generated from the keyboard strobe, from the vertical blanking signal, or from the line frequency. The only non-standard thing here is the address decoding. To avoid a separate decoder, it is mapped in I/O space at FBFC to FBFF, i.e. register B must contain OFBH, when writing or reading the CTC with an OUT (C), A or IN (C), A instruction.

Video output

The output stage has to deal with twice the bandwidth as compared to the 40-character VDU board. It must provide outputs for "wire frame" monitor and combine the output from the HRG board with that from the VDU. Further, it has to process the information contained in the attribute memory.

Inverse video is achieved using the XNOR gate FP (74LS266). This is an open collector gate and the blanking signal is introduced at this point. Dim video works as on the 40-character board. Two currents are added in the output stage in a crude D to A converter.

Underlining is performed by modifying an address line to the character generator with gates from GQ (74LS09) and GS (74LS32) so as to display a portion, not normally visible, which contains the underline.

In the output stage itself, T1 is a common base stage to amplify the HRG signal, with T2 after it as an 'emitter follower'. The open collector driver BV (7407) buffers the video signals which are added in the resistor network R18, R19, R20, and R23, along with diodes D3, D4, and D5.

Diodes D2 and D6 introduce the sync signal. D7 is a level shifter to ensure that sync goes down to zero. T3 is a final emitter-follower stage. T4 is used to disable the video signal from and to the HRG board.

Smooth Scroll

This uses hardware which has already been described.

During normal display, the multiplexer ET (74LS399) takes the dot row number from the first stage of the vertical counter FT (74LS390). When the smooth scroll is being performed, this multiplexer is switched over to take the dot row number from the latch DU (74LS173). Thus the CPU controls the rows to be displayed. In conjunction with the scroll count in CR (74LS377), the software can make the picture move by one row of dots per frame, giving the appearance of a smooth scroll.

SECTION 4

FLOPPY DISC CONTROLLER BOARD

INTRODUCTION

This section details the circuit description of the floppy disc controller board (FDC) used in all 380Z disc systems. Hardware differences between versions, for supporting different drive types, are included.

CIRCUIT DESCRIPTION

4(:

(Circuits: 380Z Floppy disc controller and SIO4, FDC1 and FDC2.)

The floppy disc controller board contains circuitry of two types:

- 1. Hardware to support a serial interface with full handshake the SIO4 port.
- 2. Circuitry for dedicated disc-controlling purposes.

The board is accessed as a block of ports in I/O space, mapped as follows:

FDS	MDS	SIO6	FDS	Board Ports	3
=====EF======	====CF=====	======4F=======			
=====EC======	====CC======	======4C=======		CTC	
=====E8======	====C8======	======48======		8251	
=====E4======	====C4======			PORT 0	
=====E0======	====C0======			FDD 1771	

1. Bus Buffering and Port Decoding

(Circuit : FDC1)

The least significant eight bus address lines BAO to BA7 are buffered by IC AQ and become IAO to IA7. The board is accessed using I/O instructions such as OUT (C), A...IN (C), A etc. The port address appears on the least significant eight address bits. IC BQ and BR (3 to 8-line

binary select line decoder) decode IA2 to IA7 to establish the map in I/O space (as above). IC BR has four outputs, CTC EN-, 8251 EN-, 1771EN-, and port 0 enable. Each of these represents a block of four ports corresponding to each function. All four outputs are ORed by IC BQ to produce IOEN-. Links 10 and 12 select whether the board is to be mapped as a full (links cut) or mini (links present) system disc-controller board.

Data is transferred via the bi-directional tristate buffer, IC AR. The direction of transfer is selected by the logic array formed from ICs CP and BP. This uses either IOEN- and IRD- to detect when one of the ports on the board is to be read by the CPU, or INT- at the first IM1- low, with IIORQ-, to reverse the direction of the buffer. IC BP /9 ensures that the direction is reversed only during IORQ operations.

Bus and CPU control signals are buffered by IC AP. On the circuit diagram these signals have the prefix I.

Port 0 is not fully decoded and occupies all four port addresses within the block assigned to it. IC BP/6,3 produces IORD- and IOWR- from IIORQ-, IRD-, and IWR-. IOWR- is active during all I/O writes within the system, and is used by IC BP/11 to enable the port 0 latch, IC BS, only during I/O writes to port 0.

Port 0

(Circuit : FDC1)

Port 0 consists of an 8-bit latch, IC BS, into which the contents of the ID bus may be written. It is a write-only port and cannot be read back, so a mask is held in memory of the contents. All software access to the port must be via read-modified write sequences.

Port 0 Bit Allocations:

Read	Bit	Write
-	. 7	DINT- (Force disc interrupt)
-	6	SET DRIVE EN-
-	5	MSEL (Dir/side select bit)
-	4	SSEL (Side select bit)
-	3	DS4 (Motor on)
-	2	DS3 (Drive select bit 2)
-	1	DS2 (Drive select bit 1)
-	0	DS1 (Drive select bit 0)

CTC Usage

(Circuit : FDC1)

IC DQ on the FDC board is a Z80A CTC. It is fully supported and is used extensively for both disc control and SIO4 implementation. It occupies a block of 4 channels, each of which is uniquely decoded by IAO and IA1 in

I/O space. For all normal applications used by the monitor, interrupt requests are not generated although provision exists for future expansion.

Channel 1: Drive enable timer. Used for drive software timings

Clock input: 64ms with DRIVE ENABLE-

Channel 2: Head load timing register. Used for drive software

timings.

Clock input: 2ms with HLT and HLD

Channel 3. Clock generator for UART Baud rate (SIO4)

Clock input: 2MHz

Channel 4: Clock input. 64ms

For disc control applications the CTC is used under software control by disc I/O routines in the monitor to generate disc primitive timings, i.e. DRIVE ENABLE, HLD delay etc. Flip-flop IC ES is used extensively to implement the timing of these signals. The CTC is clocked from the system 4 MHz buffered clock, ICLK2.

8251 Usage SIO4 (SIO6)

(Circuit : FDC1)

To implement a full V24 RS232 serial port, a dedicated UART IC, ER (8251), is used. This makes for very simple operation. Access to and from the UART by the CPU is through the block of ports occupied in I/O space. Input/Output from the UART to the serial port is via RS232 level drivers/receivers, ICs AV and BV. Control of data exchange in the port is under software control by the CPU, and baud rate for transfer is controlled by the rate of the TXC and RXC clock inputs. These are commonly derived from the CTC channel 2 after monostable IC DU produces active 'low' clock pulses of duration 1.5 us (approximately). Connection to the external peripheral is via J1.

2. Dedicated Disc Controller Circuitry

(Circuit : FDC2)

Disc I/O is largely handled by a dedicated IC controller, the FDD 1771, which occupies IC position CS. Access to the controller is via the block of ports which it occupies in the I/O map. Disc control outputs are buffered by open collector driver ICs AS and AT. Inputs are pulled up via 150 Ohm resistors to +5V, then buffered by IC AU. Links are clearly marked on the circuit diagram where hardware differences between full and mini-disc systems exist.

Apart from the FDD 1771 and support, a DATA/CLOCK separator circuit is included. This separates interleaved 'data' and 'clock' pulses from the disc drive READ DATA input into the FDD and FDC inputs to the 1771. It operates in the following way: an active 'high' clock pulse (FDC) is inverted (IC ET/8) and loads a 4-bit binary counter (CT) with 12. The counter counts up with a clock period of 250ns (full system) or 500ns (mini system) and places its count output in a BCD to decimal decoder (DT). When the count is zero, the zero output of DT goes 'low' and is used to set an S-R flip-flop (ET) whose outputs are DATA WINDOW and NOT DATA WINDOW. ET is reset when the binary count reaches 7 and DATA WINDOW is inverted until the next clock pulse, and the cycle is repeated.

Data and clock pulses (interleaved) are taken from the disc drive and passed through a Schmitt-trigger buffer, then through a monostable of time constant 120ns (approximately), before being ANDed (EU) with DATA WINDOW and NOT DATA WINDOW. The resulting outputs are separated 'data' and 'clock' pulses, FDD and FDC. (CU is used to set the phase of DATA WINDOW using the sector header before the sector identifier).

IC BT is used to multiplex direction and side-select information according to MSEL in port 0. Direction is decoded on the drive to be active with STEP, otherwise side-select information is assumed.

SECTION 5

INTELLIGENT DISC CONTROLLER BOARD

INTRODUCTION

This section describes the low-level hardware operation of the intelligent double-density disc controller board (IDC). The overall design objectives are first examined, followed by the general method by which each individual block or module is used. Then the detailed working of each module is considered in some depth.

Finally, the on-board firmware together with the option ROM interface is covered with the same top-down approach.

DESIGN OBJECTIVES

The IDC board was conceived as an improvement over the present disc controller board (FDC) in terms of storage per disc, speed and ease of use. The storage capacity has been increased by using double-density MFM recording and also by allowing for the use of 96 TPI mini-drives. Due to the use of MFM data recording the data is read from the rotating disc at twice the rate previously managed, and also, due to the use of on-board data buffering, the data throughput has been increased considerably in most uses.

As the board is intended to replace the present FDC, a serial channel is included with the same connections to the outside world. As a more modern serial chip has been used on the IDC than on the FDC, there are, in fact, two independent serial channels.

Another objective is that the board should be capable of working with a LINK 480Z. This has been made possible by allowing communication with the host processor (380Z or 480Z) through either the parallel (Z50) bus or one of the serial channels.

As the board is required to work with frequent interrupts, such as in a network server, it should carry out it tasks autonomously and without failing if interrupted during a data transfer. This is achieved by having an on-board Z80A microprocessor to handle the sectors coming from, or going to, the disc in real-time, and by transmitting the data between the host processor and the IDC under software control.

THE HARDWARE

(Circuits:

380Z Bus Interface and Decode: DC 1/4
Disc Drive Interface: DC 4/4
CPU, Serial Interface & Clocks: DC 2/4
Memory, Wait State and Internal Decode: DC 3/4)

The circuit consists of several clear-cut modules together with a small amount of TTL 'glue' to interface the various modules with each other. The main modules are as follows:

• Bus Buffering: to connect the board to the 380Z Z50 bus.

• Bus Interface: the method of transfer of data and commands to the 380Z. This includes two sub-modules:

1. Data and status registers.

2. Wait-state generation and time-out protection.

• External Decoding: to decode the I/O ports used by the 380Z.

• Clock Generation: to generate all clocks for the system including those for the serial interface, CPU and disc controller.

• Serial Interface: two channels of RS232 with buffering.

• Memory: on-board RAM and EPROM.

• Internal Decoding: to decode the I/O ports and memory used by the Z80A on the IDC board.

on the 1bc board

• Control Ports: to hold static values which control the disc drives.

• Disc Control: which consists of two sub-modules:

1. FDC chip and buffers.

2. Data Separator.

These various modules will now be described in more detail.

Bus Buffering

This consists mainly of three 74ALS1244N uni-directional buffer chips (IC 5, IC 10 and IC 11) to receive the addresses, and one 74ALS1245 bi-directional buffer chip (IC 4) which is used for the data transfer channel. In addition to these there is one element of an open-collector inverter (IC 3) which drives the WAIT line on the bus, and a three-input AND gate (IC 29) for the interrupt-priority daisy chain. The interrupt signal INT- from the CTC is also buffered by one segment of IC 1/4 to produce the BINT- signal.

Both the uni- and bi-directional buffers are permanently enabled with the direction control on the bi-directional buffers being driven by a BDIR-signal from a PAL (Programmable Array Logic) 12L6 (IC 19). BDIR- is 'low' when (i) the 380Z is reading anything on the IDC and (ii) the IDC is in the process of an 'interrupt acknowledge'. Otherwise BDIR- is 'high'.

The addresses and control lines can be connected to the bus of the IDC processor instead of the host 380Z, so that the 480Z version of the board will have access to the externally mapped ports; notably the CTC and SIO.

Bus Interface

(Circuit: DC 1/4)

1. Data and status ports are implemented as follows:

There are two data ports made up of two octal latches, IC 9 and IC 18 (both SN74ALS574N). One supplies data to the internal Z80 and the other supplies data to the host Z80 bus. Both are edgetriggered 'D' type flip-flops with tristate outputs. Given the correct conditions, the host Z80 writes to the IDC data port on the low-to-high transition of the signal HWR-; this signal is, in turn, enabled by signal DRD- and so data is transferred to the internal Z80. Similarly, when the internal Z80 wants to transfer data to the host Z80, data is latched on the low-to-high transition of DWR- and is read by HRD-.

It is important that communications between processors are kept in order to ensure that both processors do not try to:

- (i) read or transfer data at the same time
- (ii) transfer data before existing data has been read
- or (iii) read non-existent data.

This is achieved by setting a status bit whenever data is written to a port. This prevents any further writing until the current data has been read by the alternate processor. If a further write is attempted, or a processor tries to read unwritten data, a 'wait' state is generated.

2. The 'wait' state generated by attempting to read non-present data (or to write to a non-cleared data port) is set and cleared by the positive edge of the relevant cycle. As flip-flops with an edge-triggered SET and an edge-triggered CLEAR are unavailable, this function has been built using the 74LS74 clock input to set the state, and an edge-detection mechanism to clear the state. The edge-detection is done on the write signal (HWR-, DWR-) by delaying and inverting the signal (to give DHWR and DDWR), then ANDing the two signals. This produces a CLEAR pulse of 125ns (less various propagation delays.)

There are two flip-flops (IC 20 A and B), one to represent the state of the data bus interface in each direction. Flip-flop 'A' is CLEAR

(HWRWT- is 'low', DRDWT- is 'high') when data is available to the internal Z80A and thus cannot be written to again by the host Z80A. Flip-flop 'B' is CLEAR (DWRWT- is 'low', HRDWT- is 'high') when data is available to the host Z80A and thus cannot be written to again by the internal Z80A.

Take the flip-flop 'A' as the example: when the host Z80A writes to the data port, the flip-flop is set CLEAR at the end of the write cycle by the edge-detection mechanism. When the internal Z80A comes to read the data port, the flip-flop is SET at the end of the read cycle using the 74LS74 edge-triggered clock input. If the host Z80A tries to write to the data port whilst the flip-flop is CLEAR (or tries to read the data port when flip-flop 'B' is set) then a 'wait' state is generated and a time-out is initiated by triggering a 74LS123 (IC 30).

If the 'wait' state persists for longer then 200us or so, a fault has occurred; the 74LS123 will terminate and cut-off the 'wait' state to the host Z80A. It is conceivable that the software could recover from this situation in some circumstances, so a flag is set (DTIMED or HTIMED) if this time-out occurs. Also, to speed up any INIR or OTIR that may be in progress at this point, further 'wait' states are disabled until the status port has been read by the host Z80A. This latter function is accomplished using a 74LS107 as the time-out flag. The 74LS107 also holds off superfluous 'wait' states by grabbing hold of the CLEAR line on the 74LS123.

(10)

The 'wait' state and time-out structure for both directions is similar except for the actual time delay used. It is possible that the host system may be interrupted (e.g. if multi-tasking) and will leave the IDC board alone for quite a while. Therefore it is desirable to have a long time-out period for the IDC board and avoid the need for dynamic RAMs. Since the initial IDC design there has been a great improvement in communications software. Consequently, 'wait' states and 'time-outs' are avoided, especially on standalone 380Z-D systems where HRG RAM could easily be corrupted.

External Decoding

(Circuit: DC 1/4)

The bus direction signal BDIR- is decoded by six address lines, IA2 to IA7, together with control signals IIORQ, IWR and IRD. This is done to:

- (i) enable the CTC and SIO (CTCEN- and SIOEN-)
- (ii) read the host Z80A status port (HSTRD-)
- (iii) read the internal Z80A data port (HRD-)
- and (iv) write to the host Z80A data port (HWR-).

The PAL decodes I/O ports as follows:

CTC EOH to E3H

E0 :	CTC	channel	0	(SIO channel B Rx/Tx clock)	-	read/write
E1:	CTC	channel	1	(SIO channel A Tx clock)	-	read/write
E2:	CTC	channel	2	(SIO channel A Rx clock)	-	read/write
E3:	CTC	channel	3	(completion interrupt)	-	read/write
				SIO E4H to E7H		

E4:	SIO	channel	A	data	-	read/write
E5:	SIO	channel	A	control	-	read/write
E6 :	SIO	channel	В	data	-	read/write
E7:	SIO	channel	В	control	-	read/write

I/F Status E8H to EBH

E8:	IDC	interface	status	(Port	2)		read o	only
E8.	IDC	reset				-	write	only
E9 :	IDC	reset				-	write	only
EA:	IDC	reset				-	write	only
EB:	IDC	reset				_	write	only

I/F Data ECH to EFH

EC:	IDC	interface	data/commands	(Port	1)	- read/write
ED:	IDC	interface	data/commands	(Port	1)	read/write
EE:	IDC	interface	data/commands	(Port	1)	read/write
EF:	IDC	interface	data/commands	(Port	1)	<pre>- read/write</pre>

If the host tries to write to the interface status port, both the signals HWR- and HSTRD- are generated, which cause the IDC board to be reset.

Clock Generation

(Circuit: DC 2/4)

The clocks generated on the board fall into three classes:

- Standard drive clocks of 1MHz, 2MHz and 4MHz
- A special drive clock of 4MHz
- "Times 16" baud-rate clocks with programmable frequencies.

A basic 8MHz crystal oscillator (XTAL, IC 45) is used to generate the initial timing. This signal is then buffered and passed to a divide-by-2, then 4, then 8 counter (half of a 74LS393 (IC 28)) to generate the standard 4MHz, 2MHz and 1MHz clocks respectively.

The 4MHz signal is passed through an invertor (IC 45/9) with a 330 Ohm pull-up to generate the CPU clock, PHI.

The 2 MHz signal is used as the trigger input for channels 1, 2 and 3 of the CTC (IC 44) which can be programmed to generate the desired "times 16"

clocks for the serial channel 'A' transmit and receive, and also for the serial channel 'B'.

Serial Interface

(Circuit: DC 2/4)

The serial interface consists of an SIO chip (IC 40) using 75188 line drivers (IC 15, and IC 16), and 75189 line receivers (IC 6, and IC 7). The signal levels on the lines are nominally +12V and -12V. The channel 'A' is selectable to use the Sync pin as Ring Indicate whilst the channel 'B' Sync pin is used for Data Set Ready. All the incoming serial control lines have 4K7 pull-up resistors to enable sensible use of the interface without the use of the handshake lines. The channel 'A' times 16 clocks are also jumper selectable to come from an external pin multiplexed with the Ring Indicate.

Memory

(Circuit: DC 3/4)

There are two sockets on the board capable of taking memory devices. One is for EPROMs (IC 47) and one for RAMs (IC 43).

The internal firmware ROM can take any sort of 5V-only EPROM, up to 8K by 8, by means of a set of links. These links are preset to take Intel-type 2764 EPROMs. The links for other devices, are as follows:

EPROM	LINKS
2516/2716	3-5, 8-10
2532	3-5, 6-8
2732	5-6, 8-10
2564	2-4, 5-7, 6-8, 9-10
2764	3-4, 5-6, 7-9, 8-10 (this is the default option)
68764	5-7, 6-8

The internal workspace and sector buffer RAM can be either a 2K by 8 or 8K by 8 RAM. The links required for these are as follows:

2K	by	8	1	-	2
8K	by	8	2	! —	3

Internal Decoding

(Circuit: DC 3/4)

The decoding for all the chips accessible by the internal Z80A (IC 46, circuit DC 2/4) is done in a 10 input, 8 output PAL (IC 46, PAL 10L8) using address lines 2, 3, 7, 13, 14, and 15 together with control lines RD-, WR-, MREQ-, and IORQ-. The PAL decodes I/O-mapped port signals FDCEN-, DSTRD-, DRD-, DWR- and CTLWR- as well as memory-mapped signals ROMEN- and RAMEN-. There are two internal control ports which are enabled by address lines A0

and A1. The decoding is incomplete and, therefore, many different codes can access the same hardware. The nominal memory and port addresses are as follows:

FDC Chip 00H to 03H

00: Status Register	- read only
00: Command Register	- write only
01: Track Register	- read/write
02. Sector Register	- read/write
03: Data	- read/write

I/F Status 04H to 07H

04:	Interface	Status	-	read	only
05:	Interface	Status	-	read	only
06:	Interface	Status	-	read	only
07:	Interface	Status	-	read	only

I/F Data 08H to 0BH

180	Interface	Data/Commands	-	read/write
09:	Interface	Data/Commands	-	read/write
0A:	Interface	Data/Commands	-	read/write
0B:	Interface	Data/Commands	-	read/write

Port 0 0EH
Port 1 0DH

Buffer RAM E000H to FFFFH Internal ROM 0000H to 1FFFH

If the ROM is enabled, one 'wait' state is generated using half of a 74LS109 (IC 23) which is cleared at the end of the cycle.

Control Ports

(Circuit: DC 3/4)

The two ports used to control the static functions of the disc drives, such as side and drive select, are edge-triggered registers. They are written with a pulse (CTLWR-) from the internal decoding PAL (IC 42) and enabled with two separate address lines.

Port 0 (IC 39, SN74LS377N) contains the signals for drive selects, side, motor monostable trigger (IC 21, SN74LS377N) and confidence LED driving. The motor signal to the drives is SET by changing the motor bit from a zero to a one. The confidence LED is switched on if bit 6 is 'high' and bit 7 is 'low'.

Port 1 (IC 34, SN74LS379N) contains both the true and the false signals for drive size, bit density, and write pre-compensation enabling, and a flag for 'IDC in use'.

Disc Control

(Circuit: DC 4/4)

1. All output signals to the disc drives are driven by open-collector chips (IC 1, IC 3, and IC 8) and input signals are received by Schmitt-trigger buffers (IC 2) with 150 Ohm pull-up resistors (S1). The FDC chip used is the 1793 (IC 41) or equivalent which can handle 5.25-inch or 8-inch discs in single or double density, depending on the settings of two signals controlled from Port 1 (IC 34). The 74LS157 multiplexer (IC 31) is used to select the different signals for use with 5.25-inch or 8-inch drives. The links are pre-wired for a YE-Data separator but, to enable use with the SMC 9216B separator and BASF 610X drives, a set of links is provided to change the functions of some pins:

YE-data separator link LK3 2-3, LK3 5-6, LK4 1-2 SMC 9216B link LK3 1-2, LK3 4-5, disconnect LK4

For 5.25-inch drives:

BASF 6106/6108 link LK3 8-9
YE Data YD 274 link LK3 7-8

For 8-inch drives: link LK3 8-9

- 2. There are two types of data separator catered for in the design:
 - The YE-Data 3-chip set
 - The SMC 9216B single 8-pin device.

The links required to operate with the two types are described above, but it is also necessary to remove the data separator chips that are not required. Therefore, for use with the YE-Data separator, remove the 9216 (IC 32); for use with the SMC 9216B, remove the MB4393 (IC 17), MB14323 (IC 26) and MB14324 (IC 33).

The YE-Data separator also requires several other components, some of which should be of fairly close tolerance. The two monostable chains terminated by MONO8 (IC 24) and MONO5 (IC 25) require the first element to be within 5% of 2.5us and 5.0us respectively (i.e. 0.125us and 0.25us). The FDC chip requesting data is used to trigger the monostable, IC 21 (non-critical), which decreases the gain on the phase-locked loop (MB4393). The 100pF capacitor (C28) on pins 6 and 7 of the MB4393 sets the free-run frequency which should be close to 2MHz.

SECTION 6

INTELLIGENT DISC CONTROLLER BOARD

DIAGNOSTIC NOTES

How to Use these Notes

These notes look at the various problems that can occur and follow through a logical sequence to trace the fault. This may involve visual inspection of a particular section of the board or changing certain components to find the cause of the fault. On later boards most ICs are soldered directly into the PCB, so swapping of ICs is not advisable until a fault is definitely traced. This minimizes damage to the PCB. A logic probe would be useful in many places to quickly check that signals are at particular points and that they are not shorted high or low.

Use these notes in conjunction with circuit diagrams DC1/4 - DC4/4 and the board schematic diagram to help understand the fault-finding process.

All symptoms are listed below, and each is detailed on the following sheets (1-6).

Symptom

- 1. No COS prompt on power-up.
- 2. LED not on.

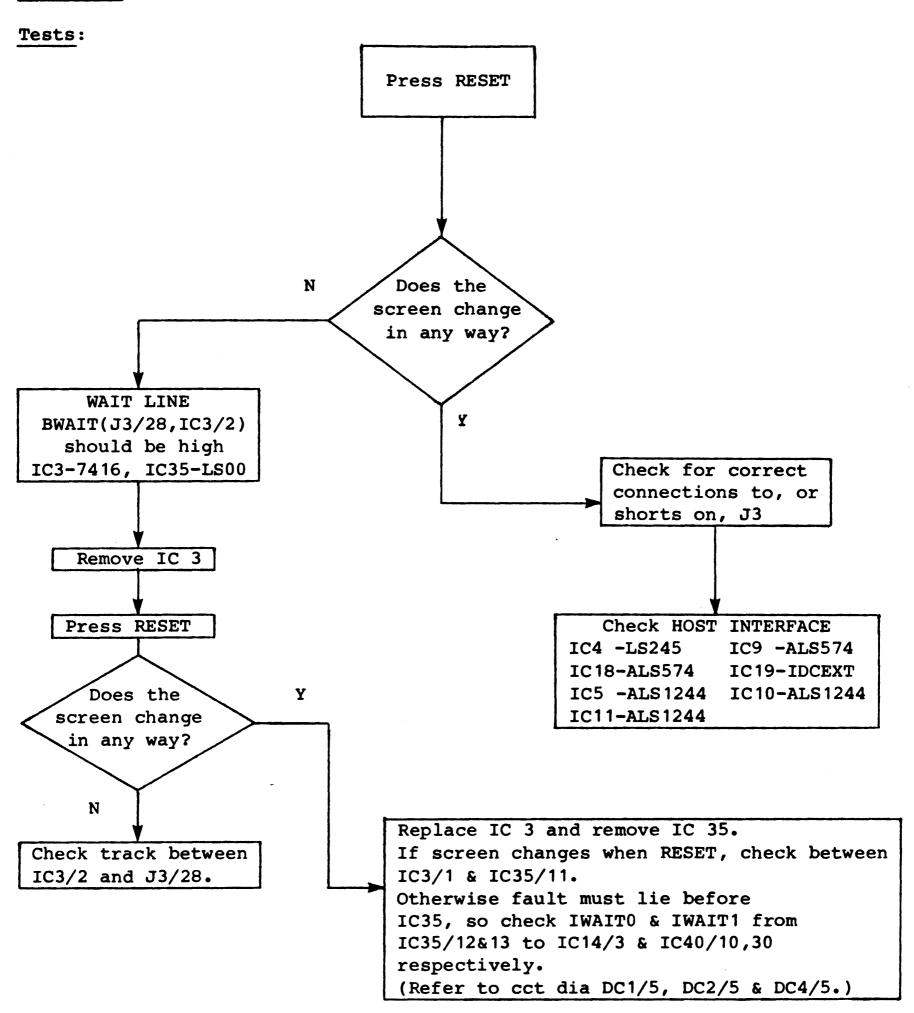

(

- 3. LED flashing FAULT 2.
- 3.1 LED flashing FAULT 3.
- 3.2 LED flashing FAULT 4.
- 3.3 LED flashing FAULT 5.
- 3.4 LED flashing FAULT 6.
- 4. LED on no boot.
- 5. No boot instant error message.
- 6. Long time to boot or does not quite boot.

Additional notes are appended to this section covering the following:

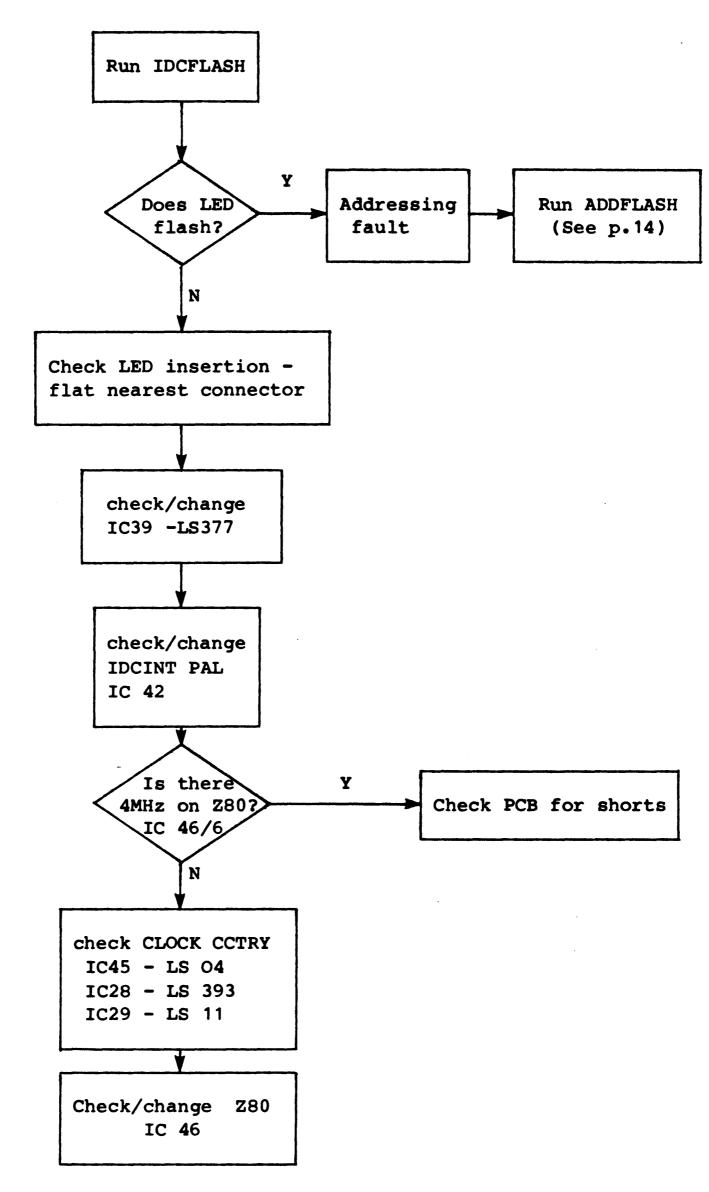

- Use of IDCFLASH
- Use of ADDFLASH
- Further helpful hints
- Z80 signals
- Modifications.

Symptom 1: No COS prompt on power-up.

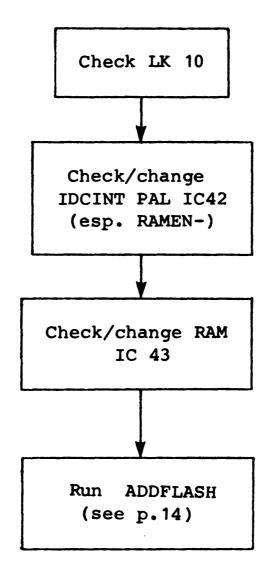

Symptom 2 LED not on. Tests:

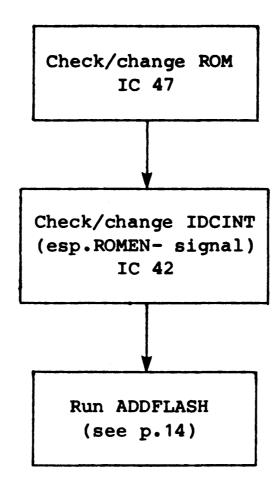

1

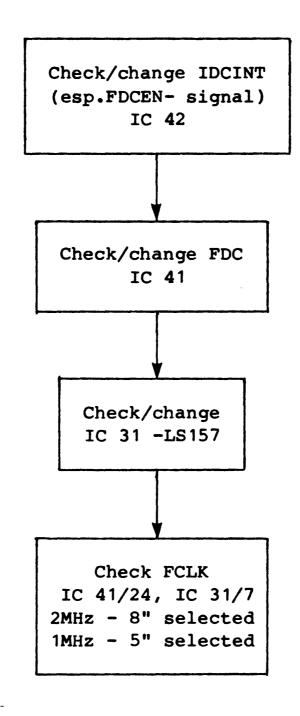

Symptom 3 LED flashing, indicating 'FAULT 2' (RAM fault).

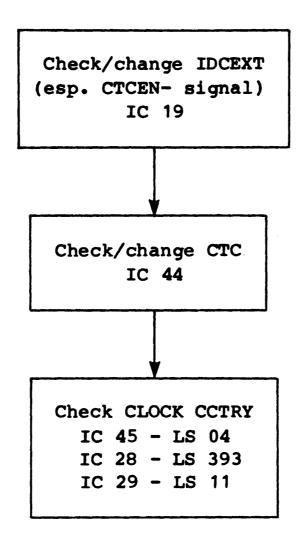

Symptom 3.1 LED flashing, indicating 'FAULT 3' (ROM fault).

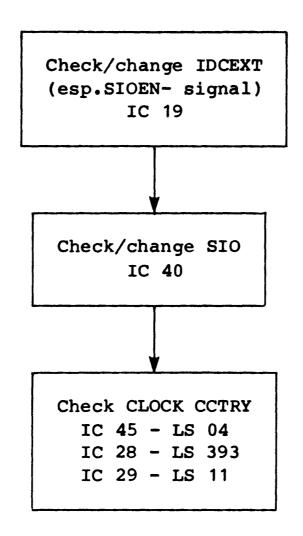

Symptom 3.2 LED flashing, indicating 'FAULT 4' (FDC fault).

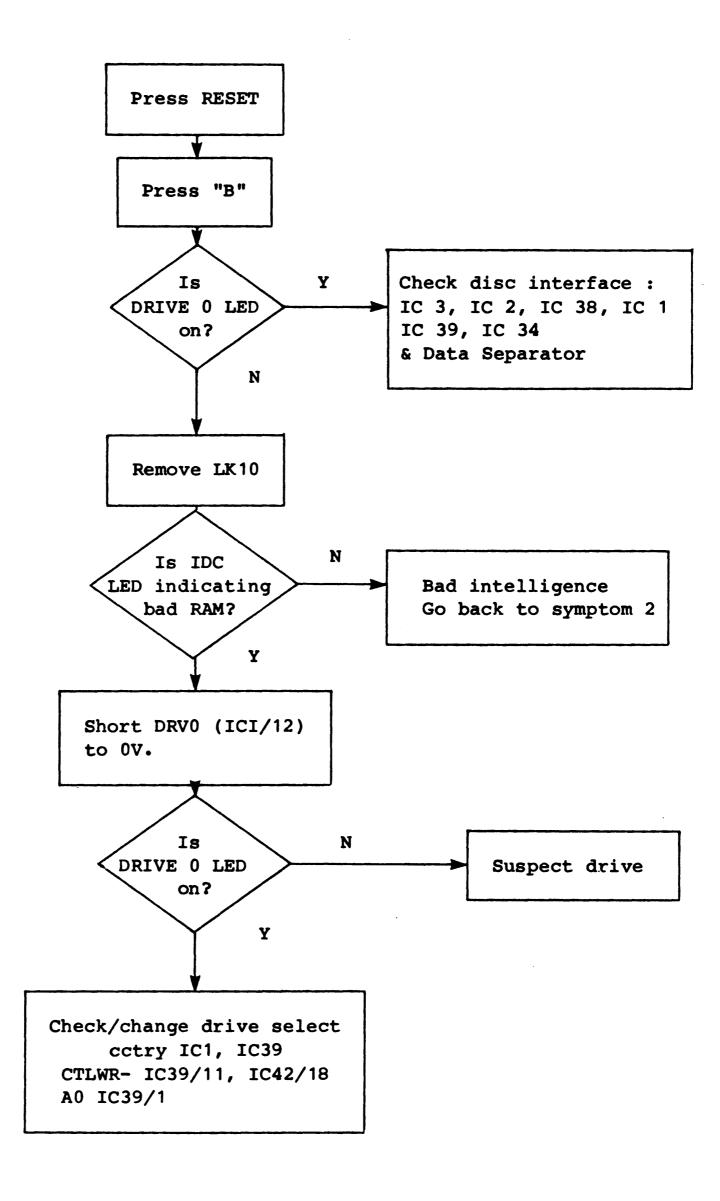

Symptom 3.3 LED flashing, indicating 'FAULT 5' (CTC fault).

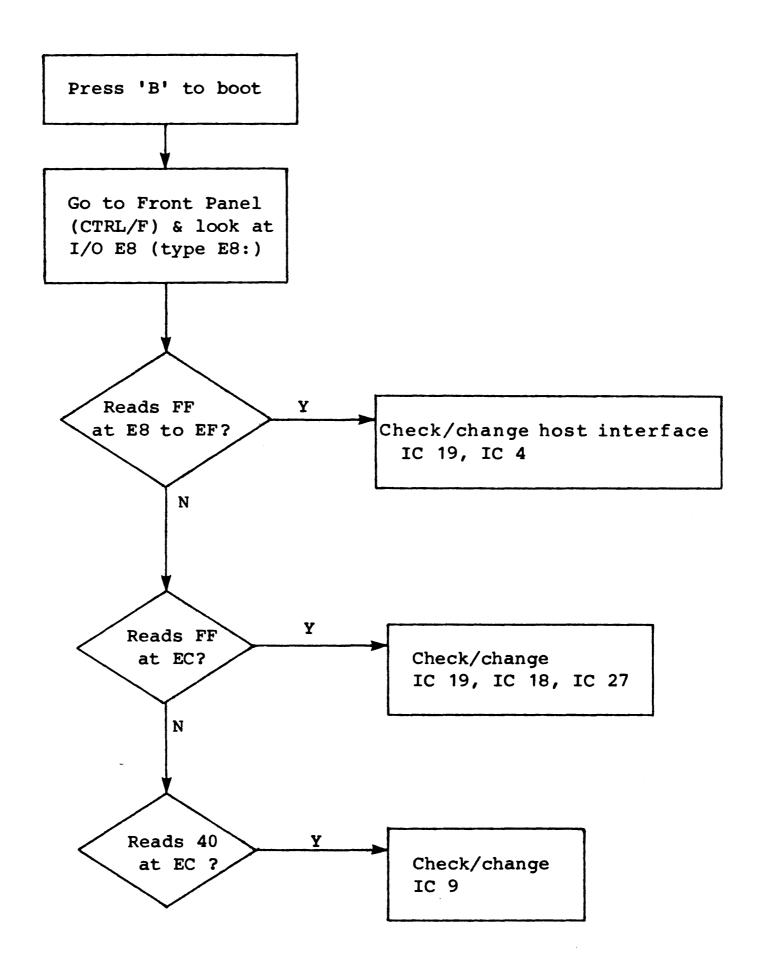

Symptom 3.4 LED flashing, indicating 'FAULT 6' (SIO fault).

Symptom 4 LED on, but system will not boot.

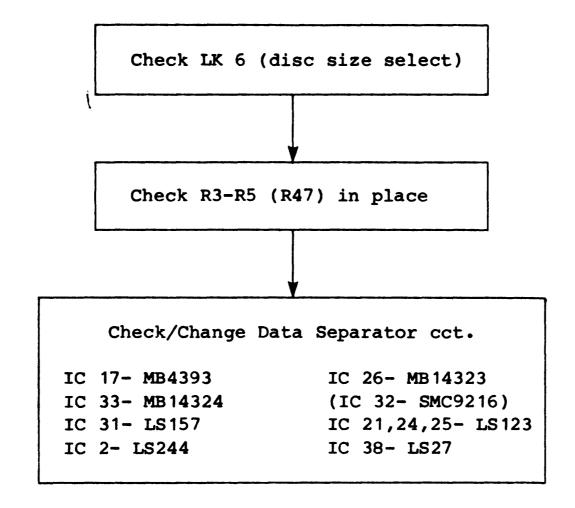

Symptom 5 No boot - error message appears instantly (380Z only)

Other Symptoms:

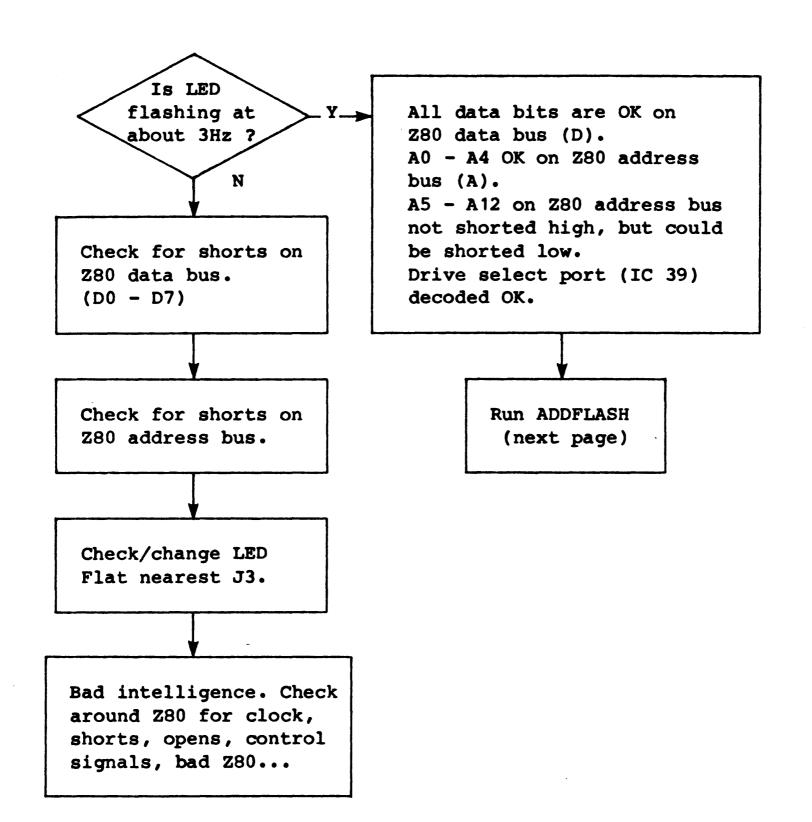

SYMPTOM		CAUSE
Breaks to Front Panel on boot	-	Probably an unformatted disc.
380Z - <boot fault!=""> or <boot err!=""></boot></boot>	-	Wrong disc or no CP/M.
480Z - <drive not="" ready=""></drive>	-	Could be faulty cable(s), faulty disc I/O buffers (IC 1, IC 2, IC 3, IC 8).
480Z - <boot error=""></boot>	-	Could be faulty disc or bad data separator. (IC 17, IC 26, IC 33, IC 36, IC 31, IC 24, IC 25, IC 32)
480Z - <disc error=""></disc>	-	Could be that the IDC is not communicating. Check SIO (IC 40, IC 6, IC 7, IC 15, IC 16) and intelligence. (Use tests in "Symptom 2".)
480Z - boot?	-	Wrong or bad disc.

Symptom 6 System takes a long time to boot or does not quite boot.

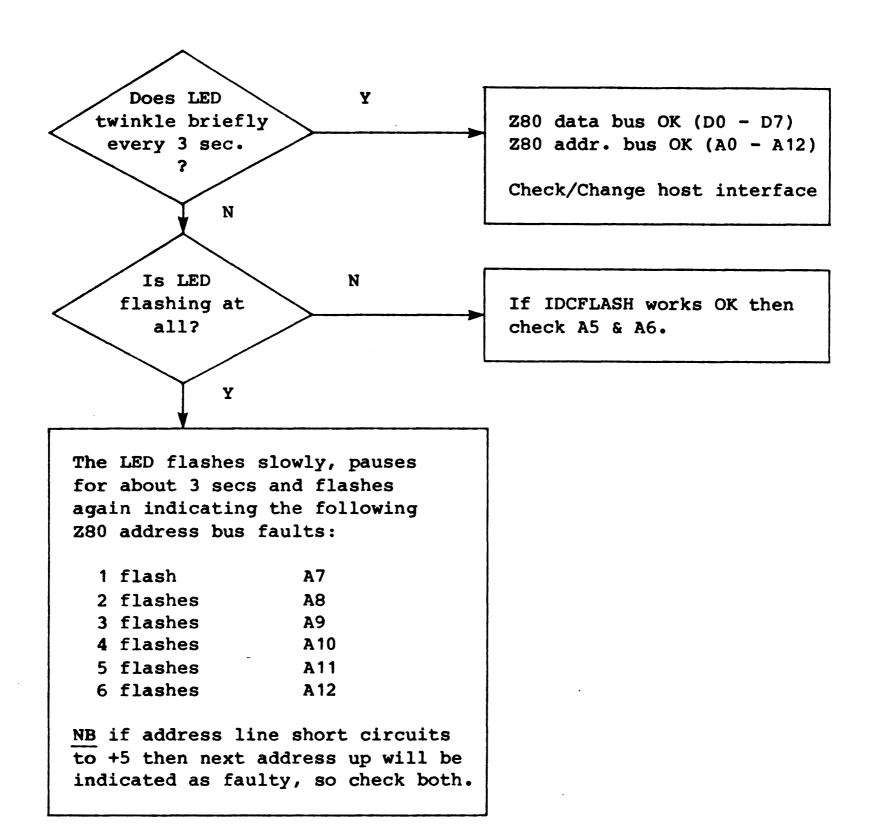

Notes on the Use of IDCFLASH

Insert IDCFLASH in ROM socket and switch on

Notes on the Use of ADDFLASH

Insert ADDFLASH in ROM socket and switch on....

Further Helpful Hints

PALs:

PALs control the selection of the various interface chips, so if a particular chip appears not to be working then the chip enable signal is a possible problem.

IDCEXT (white-purple-orange)

CTCEN-, SIOEN-, HWR-, HRD-, BDIR-

IDCINT (white-purple-yellow)

ROMEN-, RAMEN-, FDCENO-, DWR-, DRD-, CTLWR-

Interrupts:

A few devices on the IDC board generate interrupts which could interfere with the operation of the system. The SIO and the CTC put interrupts to the host, so if they start continually interrupting, the host gets tied up. This signal is IINT- and is found on IC 44/12, IC 40/5 and appears at J3/30 as BINT- after going via IC 1/3,4.

Links:

Links are worth checking as these could prevent the system working:

LK6 - select 5"/8" (link nearest edge of PCB for 8")

LK9 - select ROM type (now pre-linked)

LK10 - select RAM type (link nearest RAM for 2k RAM)

TTL:

It is worth checking that there is no LS where ALS should be.

Clock:

An LS04 is used rather than S04.

Check also that 1K2 resistors are used for R28,29.

Errors:

Occasional errors in booting or read/write could be due to R3-R5 being missing or having the wrong value. They should be 47 Ohm.

Shorts:

The most common places for shorts are where tracks go between IC pins, where there are through holes near IC pins, or where modifications have been done (especially decoupling capacitors on the back of the PCB lying across tracks).

Z80 Signals

The following signals are on the Z80 when IDCFLASH is used. A logic probe could be used to check these signals:

A7-13	1-3, 37-40	L
A0-6	30-36	I
A14,15	4,5	I
PHI	6	I
D0-7	7-10, 12-14	I
Vcc	11	H
INT	16	L
NMI	17	Н
HALT	18	Н
MREQ	19	I
IORQ	20	I
RD	21	I
WR	22	I
BUSAK	23	Н
WAIT	24	I
BUSRQ	2 5	H
RESET	26	Н
M1	27	I
RFSH	28	I
GND	29	L

H - high, L - low, I - changing

Modifications

The current modifications are:

FDS Join:

IC 39/12 to IC 21/3
IC 38/9 to IC 21/2

IC 41/20 to lower side C51 Upper side C51 TO IC 45/14

Cut:

IC 21/2 to IC 39/12 Under IC 21 to IC 21/3

Add 104 skycap:

IC 4/20 to IC 3/7
IC 28/14 to IC 28/2
IC 46/29 to IC 46/11

MDS Join:

As FDS + IC 12/11 to R26 (end near C48)

Cut:

As FDS + IC 12/11 to IC 28/13

Add:

As FDS.

SECTION 7

NETWORK TRANSCEIVER OPERATION

DESCRIPTION

A transceiver contains circuitry to encode and decode NRZI data, detect carrier and collisions, and to isolate the common bus from the station electronics and power supply. Data "modem handshake" lines, power, and an 8MHz clock are provided by the station. The station SIO transmits or receives a SDLC switched packet with a preamble and postamble of flags, as defined in the packet descriptions.

To transmit, the SIO asserts RTS and the transceiver asserts CTS, if there is no carrier detected. If there is a carrier detected, (i.e. a packet is being transmitted on the common bus) the CTS signal is delayed until the network is idle, provided RTS is not withdrawn. The transceiver provides an 800kHz clock to the SIO separate from the 8MHz clock. Data from the SIO to the transceiver is clocked on positive edges of the 800kHz clock and data from the transceiver to the SIO is clocked on negative edges. When CTS becomes true, the SIO will start transmitting the packet and, upon completion, will remove RTS. If a collision is detected, the transceiver must negate CTS and jam the network with a logic 1 to ensure that other transceivers detect the collision. RTS will be negated by the SIO in response to the collision detection.

The transceiver contains a 'watchdog' monostable which is re-triggered by RTS and which is used to limit the transmission time of the transceiver to the maximum packet length. The watchdog period has been set to 30us on Research Machines' transceivers to allow for future use of 2K packets. The transceiver may only transmit onto the common bus while RTS and the watchdog are asserted.

When not transmitting, the transceiver is in receive mode, constantly monitoring the common bus. When packets are detected, the transceiver synchronises the 800 kHz clock to the received clock and provides this and the received data to the SIO. When the common bus is idle, the transceiver must provide a logic 1 data level to the SIO.

DTR is used as a test mode signal. When asserted by the SIO, the transceiver should assert DCD to show its presence. When DTR is asserted and a collision is detected on the common bus between two other transceivers, DCD should be negated for the duration of the collision.

Collision signals should not be generated by a transceiver in receive mode disconnected from the common bus cable.

To disable an internal transceiver, Research Machines' external transceivers should ground the 'transceiver present' line on the network interface.

380Z NETWORK INTERFACE BOARD

This board is a multi-purpose board and may be configured either as a Network Interface Board (NIB) or as a Dual Serial Interface Board. The relevant circuit diagrams are :-

380Z-NET-1 Version I 30th March 1982 380Z-NET-2 Version F 30th March 1982 380Z-NET-3 Version H 30th March 1982 380Z-NET-4 Version B 30th March 1982

In this configuration, as a Network Interface Board, it will upgrade a standard 380Z into a network server when used in conjunction with a 380Z Internal Transceiver Board or an external transceiver.

The serial interfaces are based around the dual-channel Z80-SIO which is capable of operating under various asynchronous and synchronous protocols at baud rates not exceeding 800kHz. Both channels are capable of polled or interrupt-driven operation, or operating under DMA or wait-state control. Channel A is hard-configured to be a network interface port and Channel B as an RS232 serial port.

The SIO may be supported by a Z80-DMA which can be triggered by either of the SIO channels under programmable, or soldered DIL, header selection. The DMA is fully buffered to the Z50 bus and is expandable to allow multiple DMAs in the 380Z. The DMA may be programmed to support transfers between the SIO and memory, or memory and memory, within the 380Z. DMA support is an option not normally required, the Z80-DMA IC is omitted and the link "DMAL" connected.

Baud rate generation is supported by a Z80-CTC and standard rates of up to 38k4 baud may be used. Channel A of the SIO has links to select the send and receive baud rates. Link A selects the receive rate between CTC2 channel 0 or the transmit rate; link B selects the transmit rate between CTC2 channel 1 or the externally provided network clock rate. Channel B baud rate is controlled by CTC2 channel 2.

CTC1 is available for general system timing. An 8-bit switch register, as a read-only I/O port, is provided for power-up option use.

The Network Interface (J3)

(Circuit : NET-2)

This is based on an SIO channel operating in SDLC mode at the maximum clock rate (800kHz). Data In and Out, Clock In and Out, RTS, CTS, DTR and DCD are buffered and taken (via a ribbon cable) to either:

- a 15-way Cannon D-type connector mounted on the rear panel

 Transport of the connector mounted on the rear panel
- or an Internal Transceiver Board.

+12V DC is also provided to the interface to power the transceiver. A

multi-way cable, up to 30 feet long, connects the computer to the external transceiver. Collision status is monitored by the CTS modem input. Tx Enable is controlled by the DTR modem output.

RS232 Interface (J2)

(Circuit : NET-2)

This is similar to the current SIO-4 but with improvements. Standard data rates of 38k4 and 19k2 baud can be accommodated. The interface may be driven by polled, interrupt, or DMA operation. All the signals go via a DIL header position (Header C) to a 20-way header, and to the rear panel via a "User I/O Cable". This is a cheaper and more robust alternative to the current "SIO-4" cable. All signal and modem handshake reallocations are dealt with at the DIL header position, thus avoiding the normal confusion regarding soldering cables. The header position is prewired for normal DTE operation. To convert to DCE operation, the PCB links should be cut and pin pairs: 1-14, 2-13, 3-12, 4-11, 6-9 and 7-8 should be wired together.

Header C:

SIO Channel B	TxD	1	14	BA	RS232 signals
	RxD	2	13	BB	
	RTS	3	12	CA	
	CTS	4	11	CB	
• •		5	10	CC	
	DTR	6	9	CD	
	DCD	7	8	DF	

Timing

There is an on-board 16MHz crystal oscillator for all timing. This is divided by 26 in hardware to produce a master "times sixteen" baud clock (615kHz) from which all baud clock rates are derived by CTC channels. All CTC triggers and zero counts are taken to a DIL header position together with the master baud clock and another divided-down signal (600Hz).

CTC1 is intended for system timing interrupts (1ms, 2ms and 20ms). The most usual configuration will be prewired, but is easily changed by cutting PCB links and soldering a DIL header in Header B position.

Header B:

CTC 1		Tr0 *	1	16	Tr0 ** CTC2
		ZC0	2	15	z c0
		Tr1 *	3	14	Tr1 **
	(ZC1	4	13	ZC1
cascaded	(Tr2	5	12	Tr2 **
	(ZC2	6	11	ZC2
	(Tr3	7	10	Tr3
		600Hz	8	9	Baud Clock (615kHz)
* pr	ewir	ed to 6001	Hz	**	prewired to baud clock

1.1

Interrupts

Full-standard, priority daisy chain patching has been implemented which is compatible with all recent 380Z boards (Red = BIEI, Black = BIEO). If other boards operating with interrupts are used, the daisy chain must be connected using the interrupt patch cable provided with the board. The onboard priority is prewired at a DIL position, but may be changed by cutting the PCB links and using a DIL header. The default priority order (highest first) will be:

SIO, DMA, CTC1, CTC2

Header A:

CTC2EO	1	14	
CTC 1EO	2	13	CTC2EI
DMAEO	3	12	CTC 1EI
SIOEO	4	11	DMAEI
BIEI	5	10	SEOEI
	6	9	
DMAEO	7	8	DMAEI

DMAEO and DMAEI are shorted with a prewired link between pins 7 and 8 of Header A. If the DMA is installed this link must be cut.

Mapping

All ports are I/O mapped and controlled by a PAL. The CTCs (8 ports), the SIO (4), the DMA (1 port), switch register (1) and control port (1) are all mapped from DOH to DFH - in between the two standard FDC blocks. The PAL is designated a number, PDn, where n shows the mapping configuration. The current correct version is PD7, revision C (Red/Violet/Yellow).

```
DF

        CTC1 Channel 1
D1
D0
        CTC1 Channel 0
```

DMA Controller (omitted on standard board)

(Circuit : NET-1)

When the DMA controller is installed, two preset links must be cut: one in the interrupt daisy chain and the other in the bus-acknowledge daisy chain.

A bus acknowledgement priority daisy chain has been introduced, to enable multiple DMA controllers in one 380Z (or server). BBAI (Yellow) and BBAO (Blue) 2mm patch sockets are provided for cascading, and are similar to the Red and Black ones already in use for interrupt priority patching. A link is provided to connect BUSAK from the Z50 bus to the top of the daisy chain, and this must be connected on the first (or only) board in a DMA system.

Wait states are introduced on MREQ cycles when the DMA has control of the bus to make memory timing the same as the CPU. The Wait/Ready signals from each SIO channel are routed to either the Wait line or the DMA ready input under the control of seven bits in the control port register.

Programming the Control Port (omitted on standard board)

The WRSx signals control the Wait/Ready selection: Bit 6 is an enable and bits 5 to 0 select any of the 32 possible combinations of SIO channels A and/or B operating under Wait-state or Ready-triggered modes. The selections are in a PROM, but for fixed non-programmable operation a DIL header may be substituted for the PROM. Wait/Ready A and Wait are connected by a preset cutable link on the standard board.

Wait/Ready Header:

	1	16	
	2	15	
	3	14	
	4	13	
W/R A	5	12	Ready
W/R B	6	11	Wait
	7	10	
	8	9	

Programming the SIO and DMA

The SIO and DMA devices are treated as a series of internal registers accessible through one I/O port address. Each SIO channel occupies two ports: data (read/write) and control (seven write registers and three read registers). However, these are non-symmetrical with certain parts being common to both channels. The DMA occupies one port through which all 21 internal registers are accessed by sequences; the maximum length is five operations. Care should be taken in the initialization and programming of these devices, and the use of tables is preferred in all but the most time-critical applications.

The SIO can produce up to eight vectored interrupts (four per channel). In order of priority these are:

- Special Conditions (Receive overrun, End of frame, CRC error)
- Receive Character Available
- Transmit Buffer Empty
- External Status Change (CTC, DCD or Synch status change, Break/Abort detection, or CRC detection)

Channel A has priority over Channel B.

The DMA can produce four vectored interrupts:

- On Ready (before Bus Request)
- On Match (with a data byte)
- On End of Block
- On Match and End of Block.

Programming the CTC Baud Rate

When the CTC triggers are connected to the baud clock, standard baud rates may be generated by simple division ratios. The control bytes and time constants to provide standard rates are as follows:

07H	142	; 110	Baud
47H	0	; 150	Baud
47H	128	; 300	Baud
47H	64	; 600	Baud
47H	32	;1200	Baud
47H	16	;2400	Baud
47H	8	;4800	Baud
47H	4	;9600	Baud
47H	2	; 19k2	Baud
47H	1	;38k4	Baud

The relevant byte pair should be loaded to CTC2 channel 2.

SECTION 8

HOST INTERFACE BOARD

INTRODUCTION

This section describes the low-level hardware operation of the Host Interface board (HIB). The design objectives are considered first, followed by the general description and use of the different on-board modules.

DESIGN OBJECTIVES

When Research Machines decided to look into winchester systems, the most convenient method of interfacing to the 380Z was via the IEEE interface. This was mainly due to availability and cost of winchester drives. The first non-released systems were using 8-inch IMI winchesters with an IEEE interface. The introduction of the network system showed the full potential of the winchester, and cost and speed of access led to deeper research of the winchester market. The introduction of the 5.25 inch high-capacity winchester brought a reduction in cost. A more convenient standard interface, the SASI (Shugart Associates System Interface) was introduced to interface to the new generation of winchesters. This meant that a new board would have to be designed in order to interface the 380Z to SASI. This new board would also have to work in a heavily interrupted environment and at high data transfer speed. The hardware had to be readily available and also of relatively low cost.

The MK1 HIB was therefore introduced with extra options, namely an Option Boot ROM, 16K by 8 Static RAM, and DMA. It was soon realised that the options were adding to the cost and no real use could be found to justify the extra cost on a server. Although MK1 HIB boards went into production, no options were fitted and the basic board design was not changed. The MKII HIB has minor differences to MKI and IC positions are indicated by numbers instead of letters. (Both sets of circuit diagrams, for MkI and MkII, are included with this section).

THE HARDWARE MODULES

The HIB circuit consists of a few hardware modules together with some logic to interface the various modules. Particular attention is paid on grounding the HIB to SASI. The modules are as follows:

Bus Interface : To connect the HIB to the 380Z bus.

Bus Decoding : To decode I/O and memory-mapped ports.

Memory : The on-board RAM.

PIO chip SASI data SASI control SASI termination

A full description of these modules is given below.

Bus Buffering

The address bus is buffered by three SN74LS1244N ICs (AA, AB, and AC) and the data bus by IC AF (SN74LS1245N). The BRFSH- signal is buffered by one segment of an inverter, IC AK (SN74LS14N) and outgoing signals BWAIT- and BINT- are buffered by an open collector, IC AL (SN7407N). Priority daisy chain interrupt is serviced by two segments of IC AI (SN74LS10N).

Bus Decoding

The decoding is done by two 12-input 6-output PAL 12L6 ICs (AD and AE). Addresses A0 to A7, together with control signals IORQ-, WR-, RESET- and M1- are used to produce decoded signals (through PAL IC AD) PIOM1-, PIOEN-, MCONTROL- and IORD-. For IC AE, addresses A9 to A15 are used together with control signals M1-, MREQ- and RFSH to produce decoded signals MEMRD- and DBMEMEN- (DBEN-). Not all decoded signals are mentioned because they are concerned with the original design options. Functions of decoded signals are as follows:

PIOM1- : This signal (apart from the M1 cycles to the PIO) acts as

a PIO reset, when RESET- is present.

PIOEN- : Enables PIO for reading or writing.

MCONTROL-: Enables the four most-significant bit (MSB) addresses for

the on-board memory. The four MSB addresses are under software control and the processor will set data bits D2 to D5 accordingly. IC BD (SN74LS273N) latches signals BANK2 to BANK5 at the end of the MCONTROL- cycle (low to

high transition).

IORD- : When this signal is active, PIO is read and signal BUFDIR-

is active thus pointing data bus direction to the 380Z

bus.

MEMRD- : Indicates that on-board RAM is read by the 380Z and that

BUFDIR- is active.

DBMEMEN- : Enables on-board RAM for read/write operations. This

signal is fed through an OR gate and becomes DBEN-.

'Interrupt acknowledge' is taken care of by ICs AJ (SN74LS02N) and AH (SN74LS10N). BUFDIR- will be active when the HIB is in the process of an interrupt acknowledge or when the 380Z is reading either the on-board RAM or the PIO. The following table shows the mapping of the different ports on the HIB:

40H: PIO channel 'A' data read/write
41H: PIO channel 'B' data read/write
42H: PIO channel 'A' control read/write
43H: PIO channel 'B' control read/write

45H: PIO Deblocking RAM control write only

F800 to F9FF Deblocking RAM memory space.

Memory

\(

The on-board RAM, otherwise known as the deblocking RAM, is an 8K by 8 pseudostatic RAM D2186 (IC BG). Deblocking RAM occupies 512 bytes of memory space so it cannot all be read at once; the 380Z supplies the four MSB addresses BANK2 to BANK5 thus allowing RAM to be read or written in 1/2K chunks. This type of RAM is like the dynamic RAM but produces its own internal refresh cycles. If RAM is selected (by DBEN- going 'low' during an internal refresh cycle) pin 1 will go 'low' and a WAIT will be put onto the bus. Some types of 8K static RAM may also be used, such as the Toshiba type as used on the IDC.

Interface to SASI

The PIO IC, CA, is the primary unit for interfacing to SASI. It handles data and commands through channel 'A' and control signals from and to SASI through channel 'B'. Address line A0 is used to select the appropriate channel for data transfer between Z80A-CPU and Z80A-PIO, whilst address A1 defines the type of data transfer to be performed, i.e. data or command.

Although channel 'A' uses all 8 bits in bi-directional mode, channel 'B' bits BD0, BD1, BD2, BD3, BD6 and BD7 are used as inputs whilst BD4, and BD5 bits are used as outputs. The bus clock is fed through one segment of IC AL, an open collector buffer, with the output pulled up by a 330 Ohm resistor, to produce ZCLOCK for the PIO.

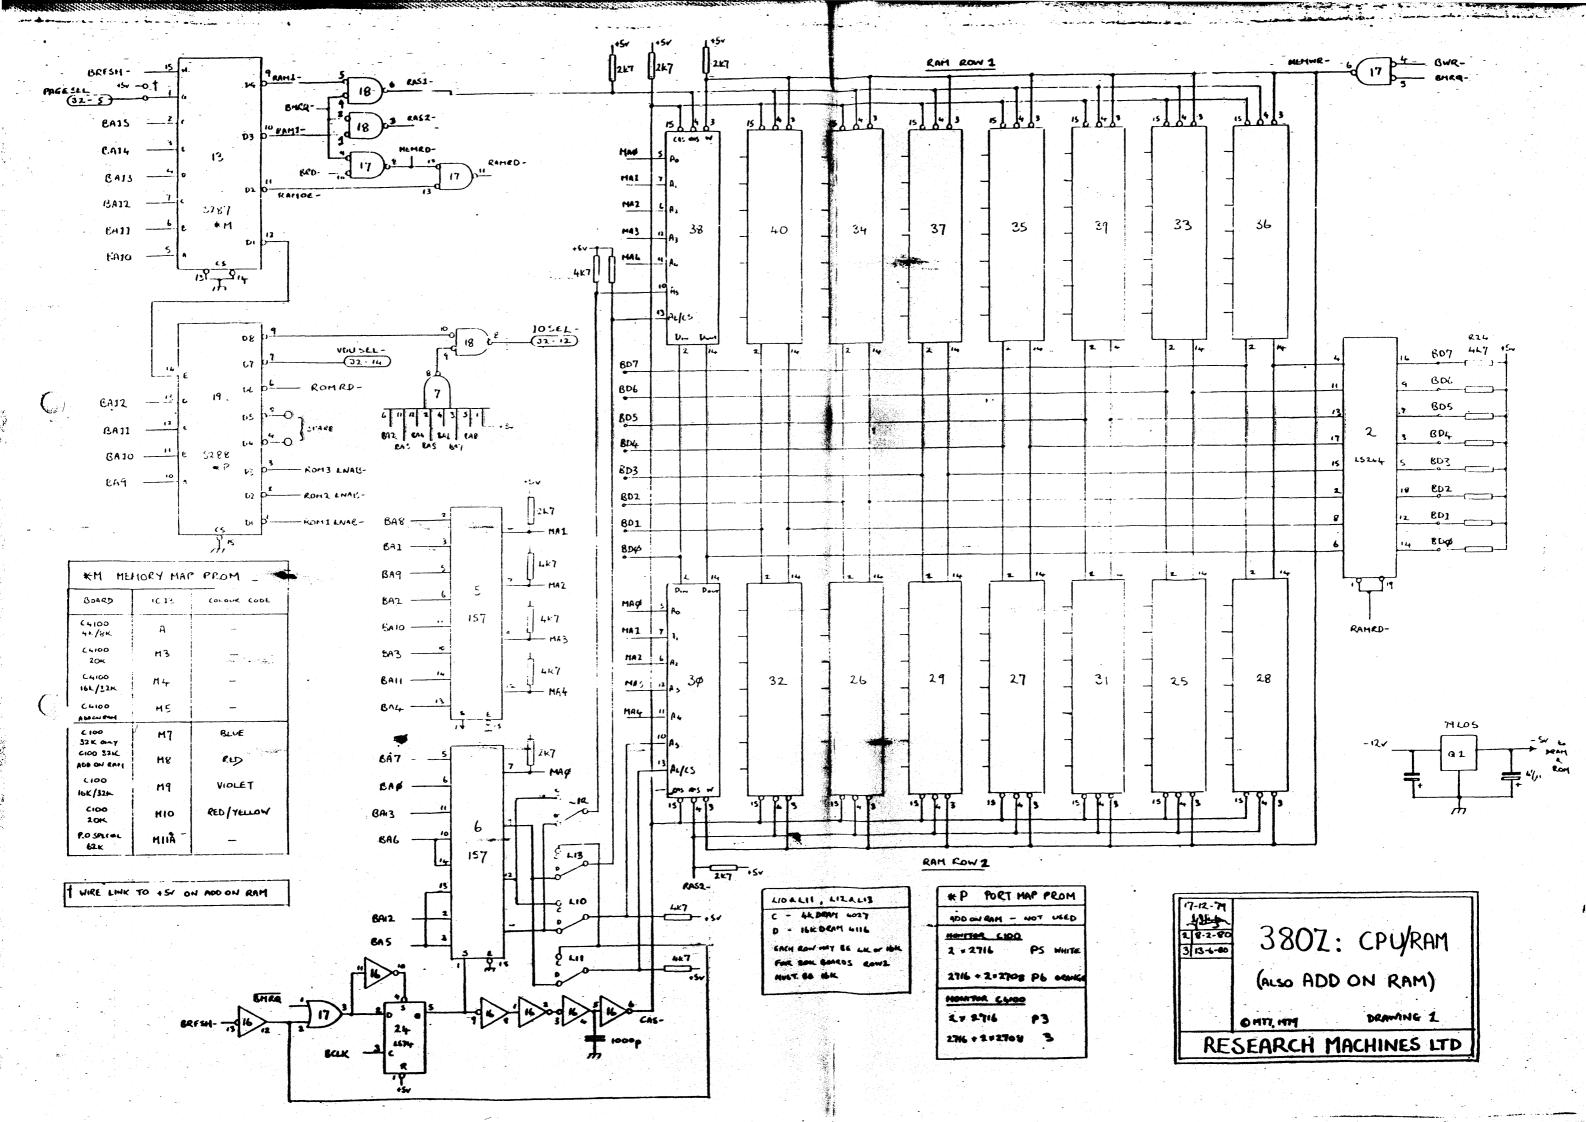

Data transfer between PIO and SASI is done via IC CB, an open collector bus transceiver (SN74LS642-1N).

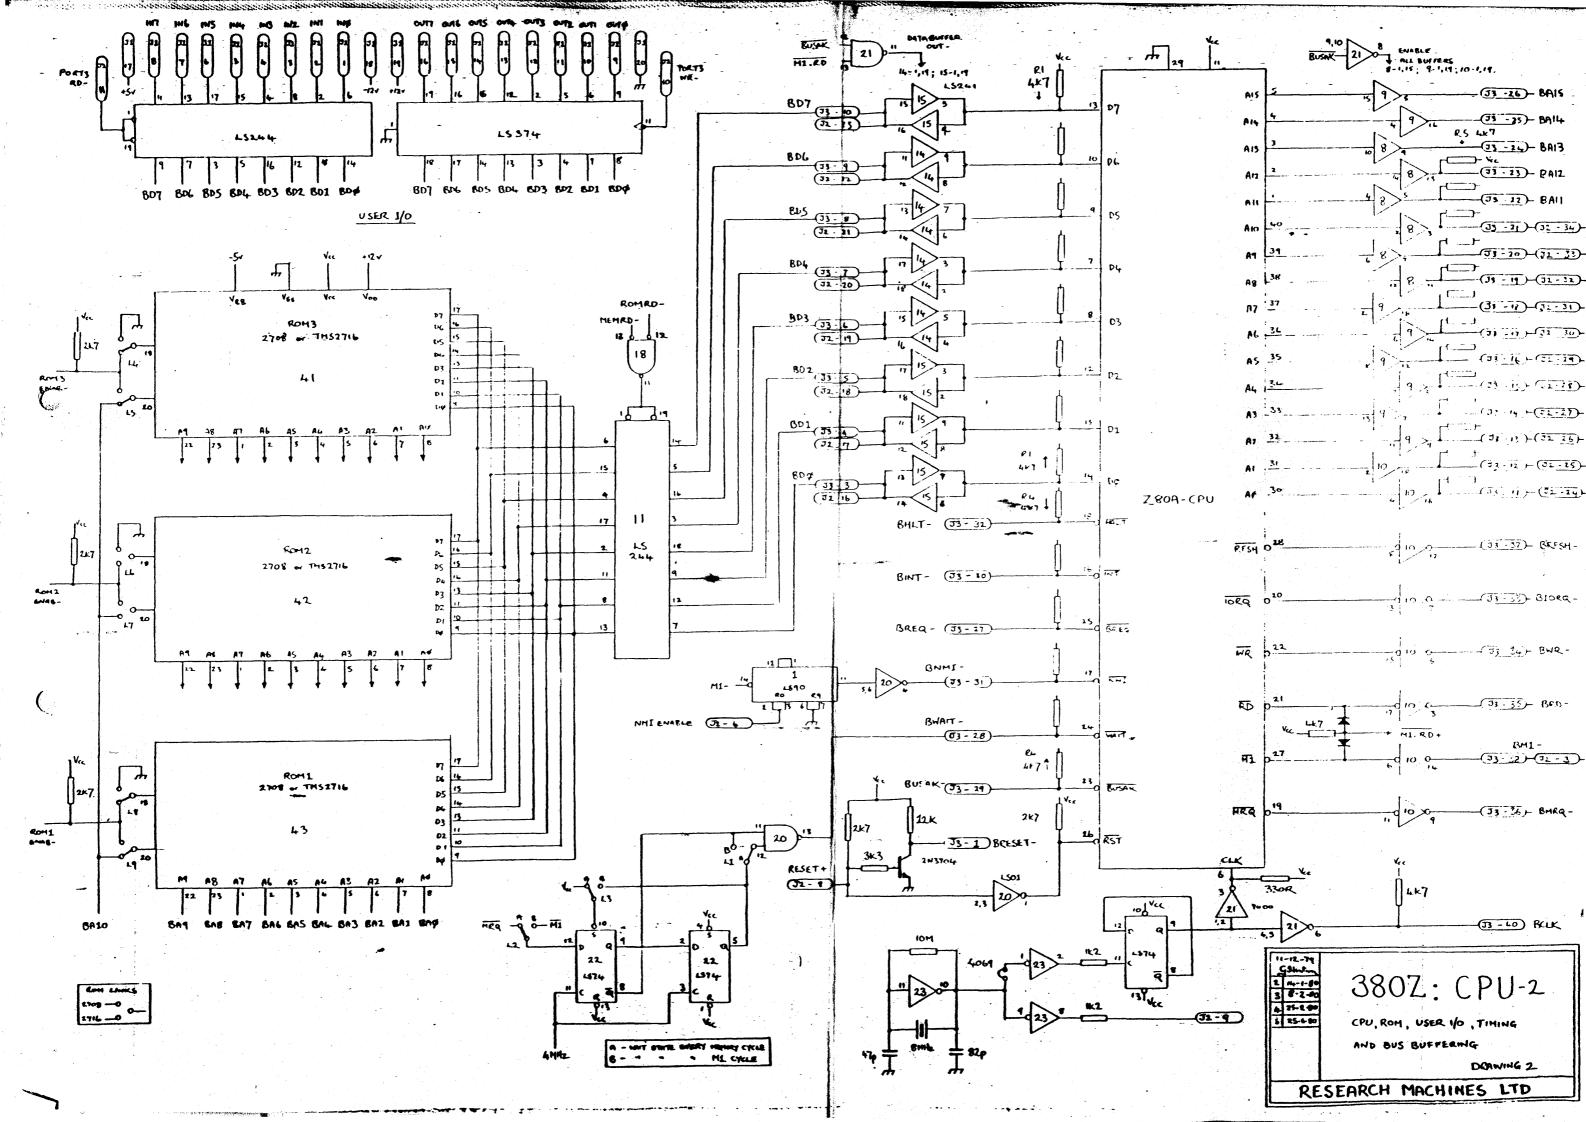

Control to and from SASI is more complicated due to the handshaking procedure. Direction of the bus transceiver is under SASI control by signal IN, but enabling will not take place at the correct time unless control signals are allowed to settle down. This is achieved by taking the acknowledge signals, i.e. select, read, and write, and delaying them by a predetermined factor, thus allowing good set-up times. The delaying takes place at IC CC (SN74LS273N) by connecting one output to the next input and clocking them through using the 4MHz clock. WRACK is delayed by a factor of two, thus becoming WRACKDEL, whilst RDACK and SELACK are delayed by a factor of three and so becoming RDACKDEL and SELDEL. IC CC is continuously reset through IC CF (SN74LS02N) by signal REQ or WRACKDEL or RDACKDEL but also allowing for a reset from the Z50 bus.

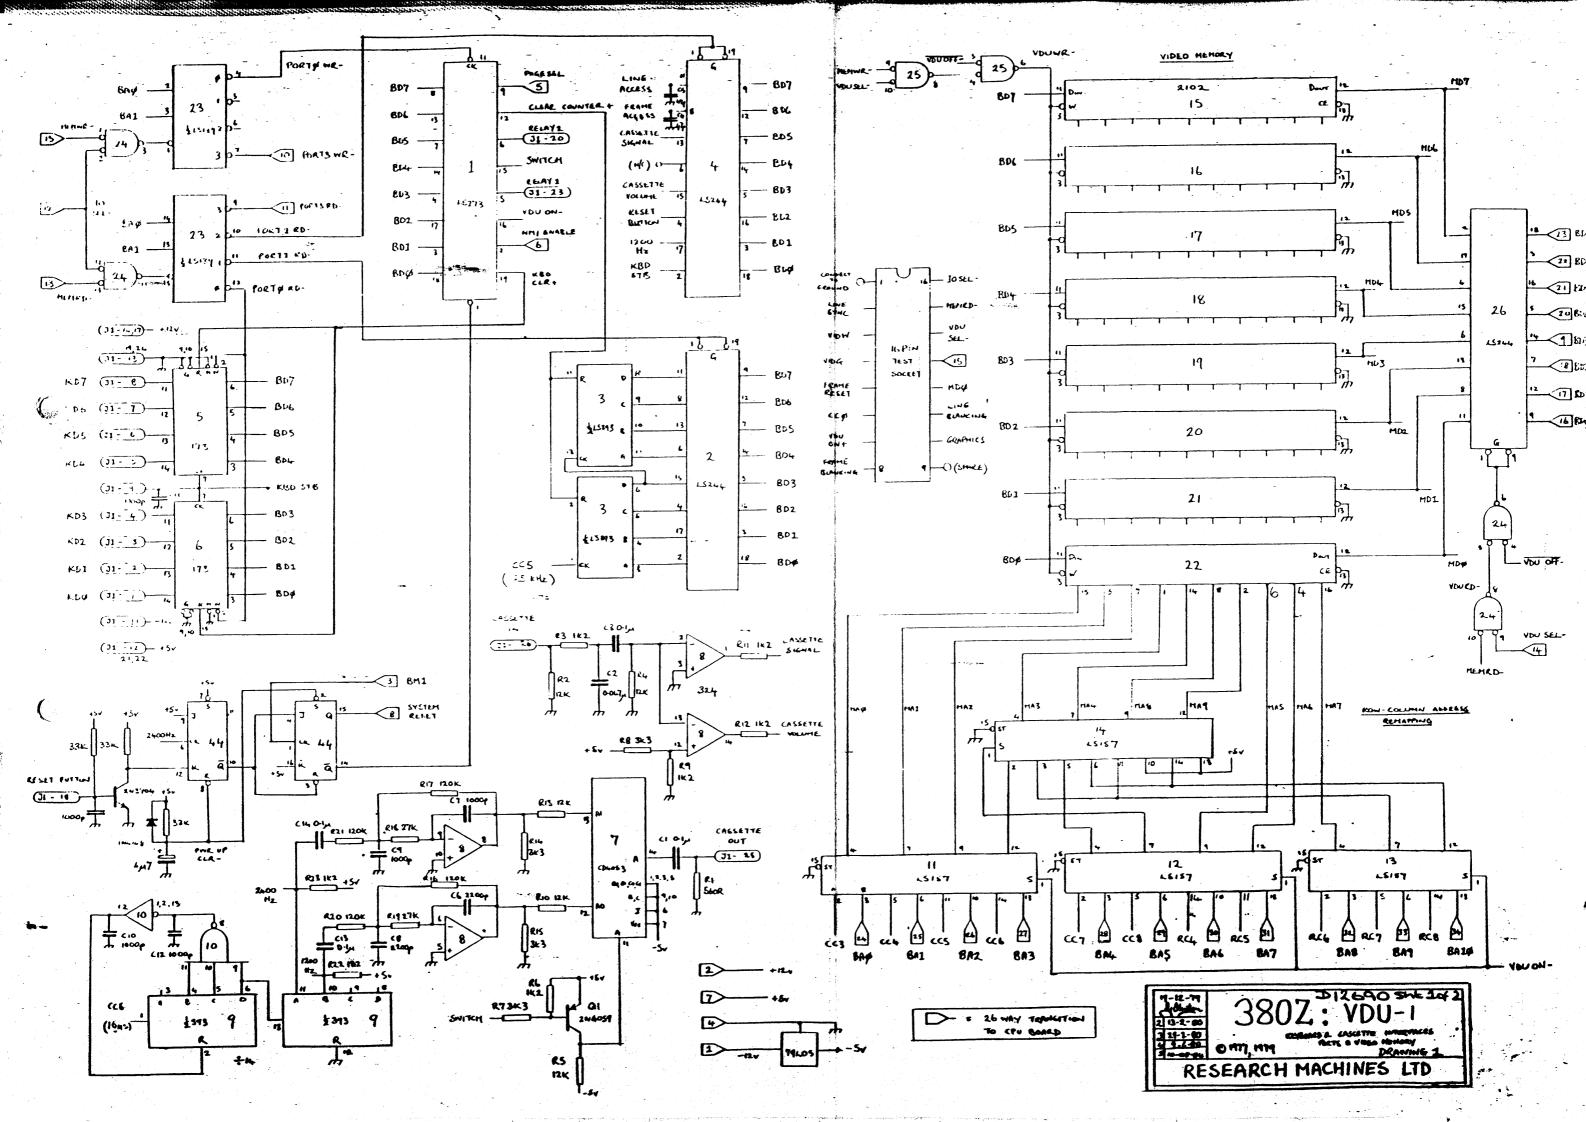

The SASI bus transceiver is enabled by signal SDBUFEN- in both directions. SELACK or WRACK enable IC CB when IN signal is 'low' (pointing to SASI) and

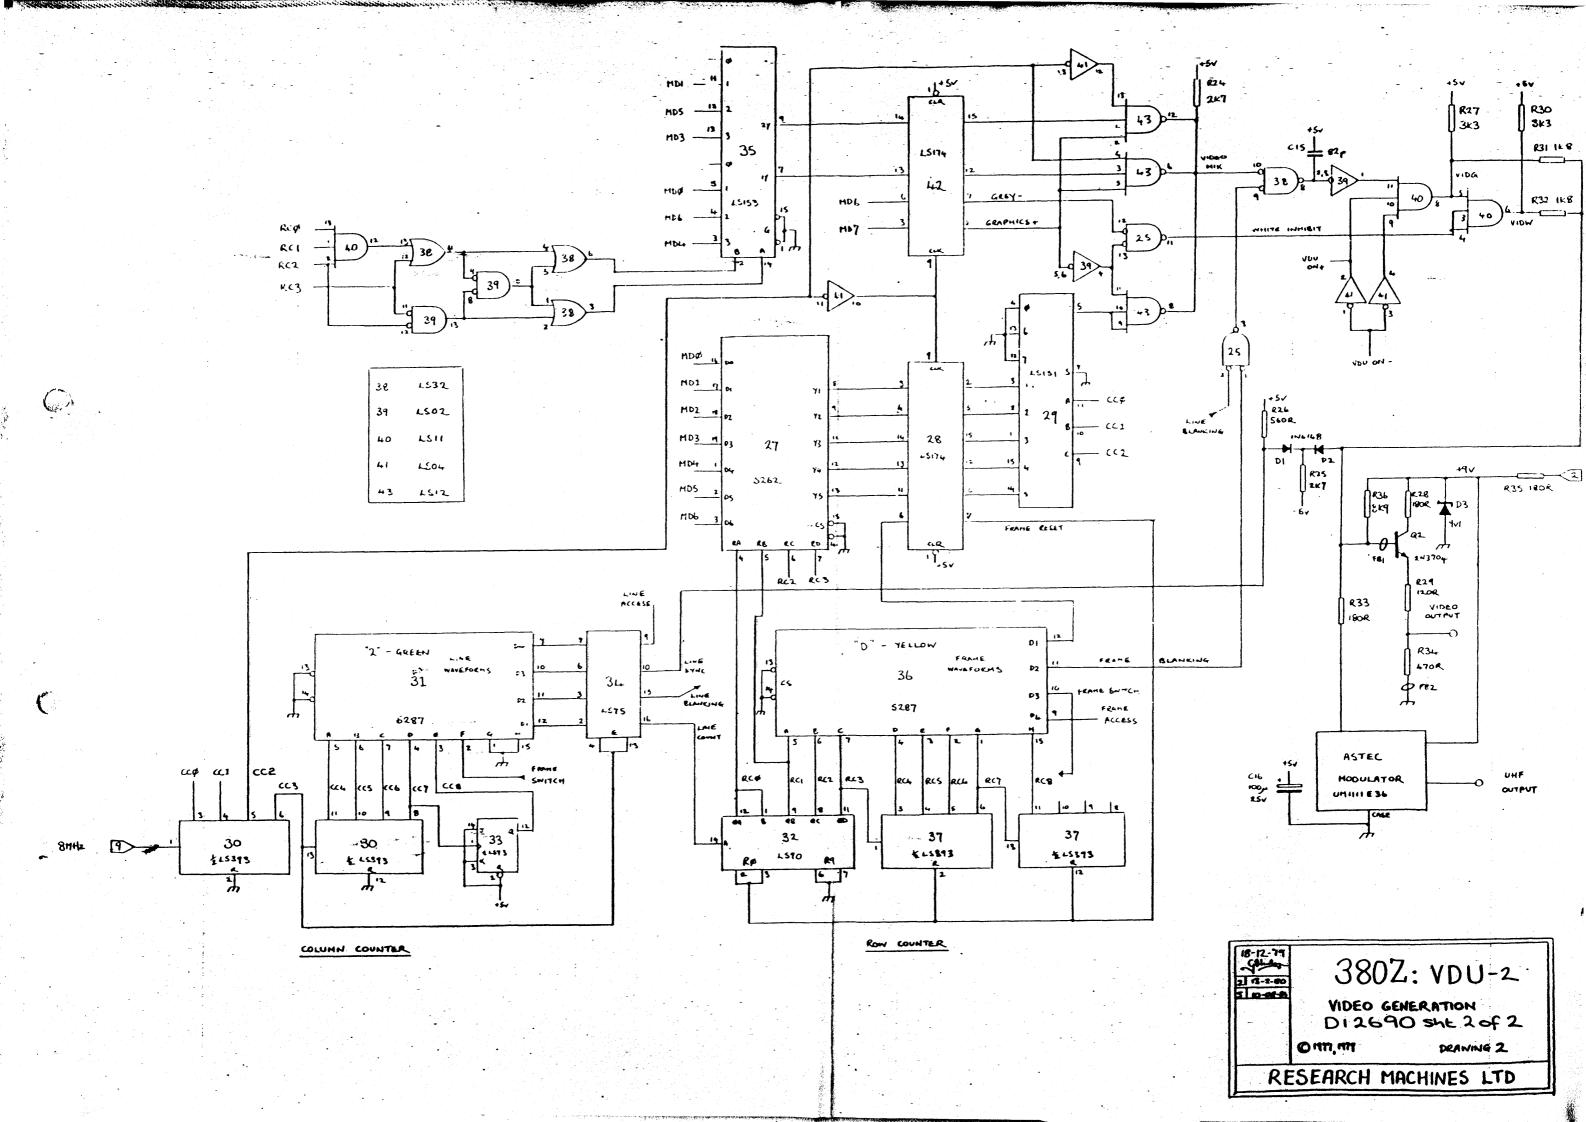

RDACK or RDACKDEL enable IC CB when IN is 'high' (PIO reading from SASI). WRACKDEK and RDACKDEL are supplying the acknowledge signal to SASI.

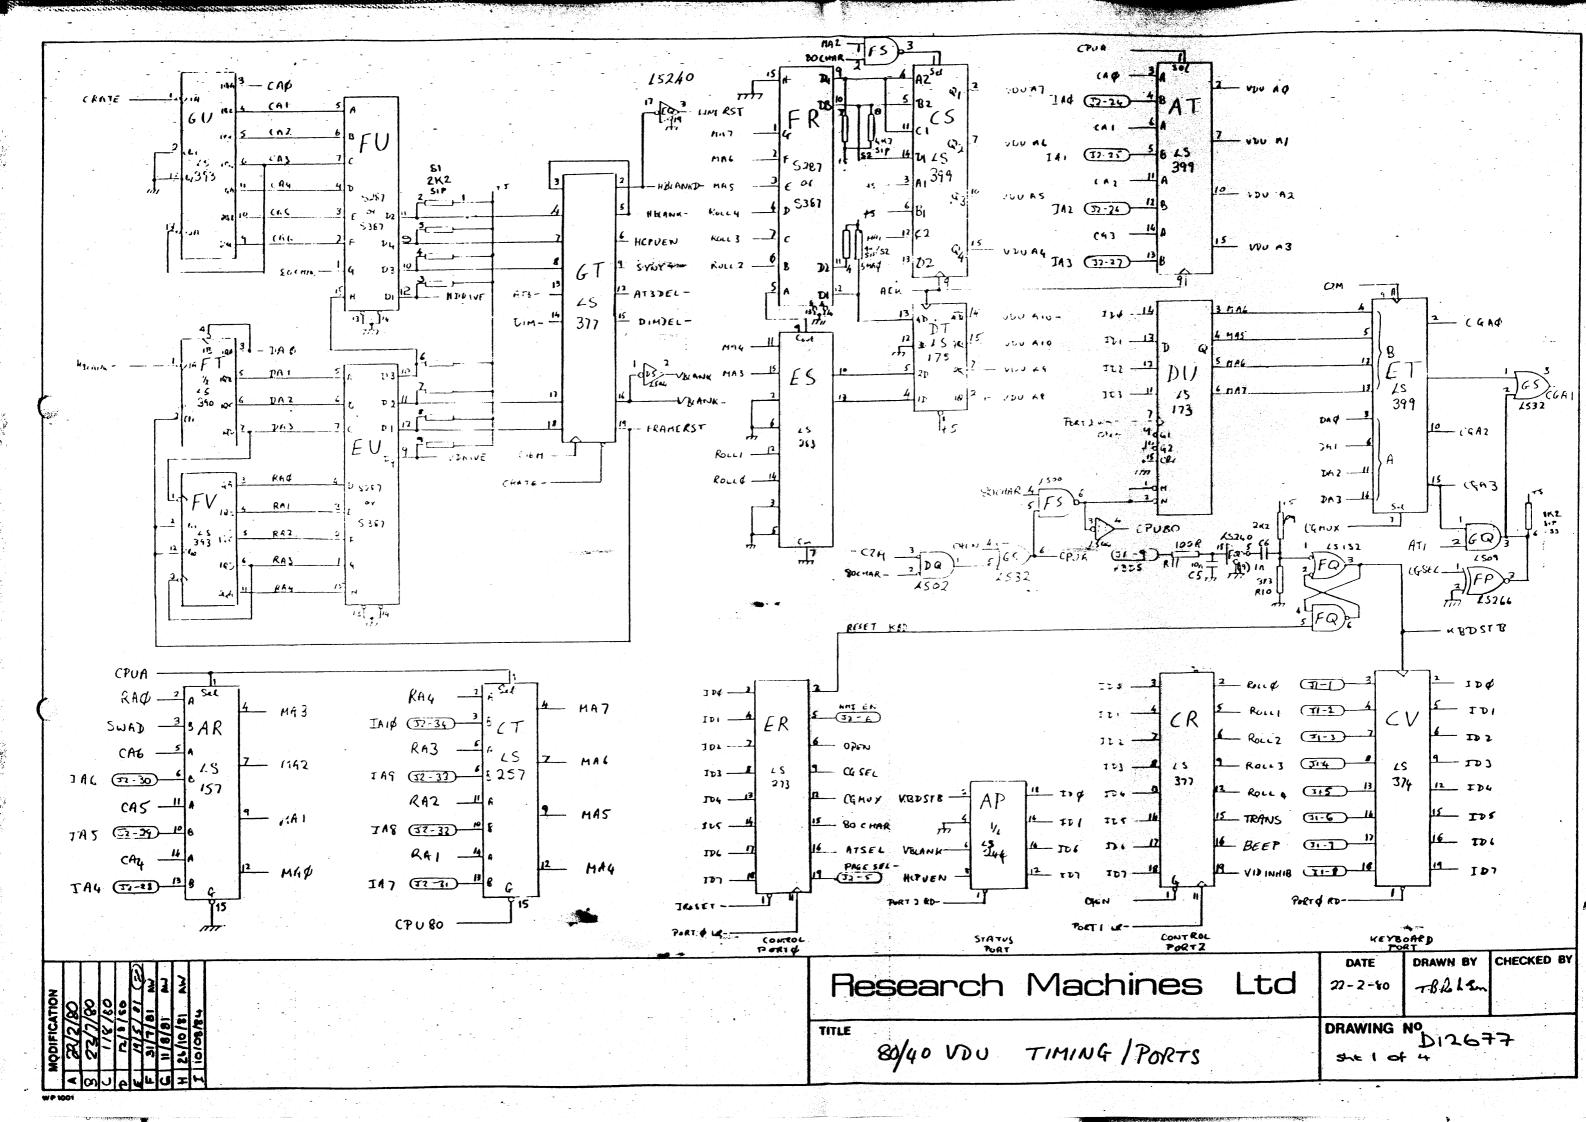

Termination is done at both sides of the transceiver (open collector outputs) by using a 4K7 resistor network, RB, at the PIO side, pulling the bus to +5V, and by a pull-up resistor network, RC (150 Ohm resistors) at SASI side and connecting to a 2.9V terminating voltage. Terminating voltage is derived using a three diode chain connected to ground by R2 (0.7V drop across each diode). Particular attention is taken for grounding SASI control signals: a 0.56 Ohm resistor is connected between SASI ground and HIB ground for ground noise elimination.
